Overview

This lecture draw heavily upon

- 2012 AEA continuing education lectures by Imbens and Wooldridge (full materials available [here](#).)
- Abadie and Cattaneo (2018)

The Evaluation Problem

- The issue we are concerned about is identifying the effect of a policy or an investment or some individual action on one or more outcomes of interest
- This has become the workhorse approach of the applied microeconomics fields (Public, Labor, etc.)
- Examples may include:
 - The effect of taxes on labor supply
 - The effect of education on wages
 - The effect of incarceration on recidivism
 - The effect of competition between schools on schooling quality
 - The effect of price cap regulation on consumer welfare
 - The effect of indirect taxes on demand
 - The effects of environmental regulation on incomes
 - The effects of labor market regulation and minimum wages on wages and employment

Typically attributed to Donald Rubin

- Observe N units, indexed by i , drawn randomly from a larger population
- Postulate two **potential outcomes** for each unit $\{Y_i(1), Y_i(0)\}$ depending on whether they receive treatment or not.
- Observe additional *exogenous* covariates X_i
- Consider a binary treatment W_i such that

$$Y_i \equiv Y_i(W_i) = \begin{cases} Y_i(0) & \text{if } W_i = 0 \\ Y_i(1) & \text{if } W_i = 1 \end{cases}$$

SUTVA

- Note there is already an important assumption embedded in this setup, the stable unit treatment value assumption (**SUTVA**).
- Assume that the outcome, in either state for unit i does not depend on the assignment of other units.
- This is likely to fail in many important settings.
- Two ways to express this:
 - No interference.
 - No hidden variations
- Examples?

① Matching

② Instrumental Variables

③ Difference in Difference and Natural Experiments

④ RCTs

⑤ Structural Models

- Key distinction: the treatment effect of some program (a number) from understanding how and why things work (the mechanism).
- Models let us link numbers to mechanisms.

The Evaluation Problem

- Two major problems:
 - All individuals have different treatment effects (**heterogeneity**).
 - We don't actually observe any one person's treatment effect ! (Missing Data problem)
 - Individual treatment effects $\tau_i = Y_{1i} - Y_{0i}$ are never observed (FPOCI)
- We need strong assumptions in order to recover $f(\beta_i)$ from data.

More Difficulties

What is hard here?

- Heterogeneous effect of β_i in population.
- Selection in treatment may be endogenous. That is W_i depends on $Y_i(1), Y_i(0)$.
- Fisher or Roy (1951) model:

$$Y_i = (Y_i(1) - Y_i(0))W_i + Y_i(0) = \alpha + \beta_i W_i + u_i$$

- Agents usually choose W_i with β_i or u_i in mind.
- Can't necessarily pool across individuals since β_i is not constant.

Structural vs. Reduced Form

- Usually we are interested in one or two parameters of the distribution of β_i (such as the average treatment effect or average treatment on the treated).
- Most program evaluation approaches seek to identify one effect or the other effect. This leads to these as being described as **reduced form** or **quasi-experimental**.
- The **structural** approach attempts to recover the entire joint $f(\beta_i, u_i)$ distribution but generally requires more assumptions, but then we can calculate whatever we need.
- Instead we often focus on simpler estimands.

Common Objects of Interest

- Population average treatment effect (PATE)

$$\tau_P = E [Y_i(1) - Y_i(0)]$$

- Population average treatment effect for treated units (PATT)

$$\tau_{P,T} = E [Y_i(1) - Y_i(0) | W = 1]$$

- Sample average treatment effect (SATE)

$$\tau_S = \frac{1}{N} \sum_{i=1}^N (Y_i(1) - Y_i(0))$$

- Sample average treatment effect for treated units (SATT)

$$\tau_{S,T} = \frac{1}{N_T} \sum_{i \in W_i=1} (Y_i(1) - Y_i(0))$$

Confounding

- Consider the *association*

$$\tau = E[Y|W=1] - E[Y|W=0]$$

- Then $\tau = \tau_{ATE} + b_{ATE}$
- Where b is the *bias*

$$\begin{aligned} b_{ATE} &= (E[Y_1|W=1] - E[Y_1|W=0])Pr(W=0) \\ &\quad + (E[Y_0|W=1] - E[Y_0|W=0])Pr(W=1) \end{aligned}$$

- So the bias disappears only if the potential outcomes are independent of treatment assignment.
- This is called **unconfoundedness**.

Estimation under unconfoundedness

Assumption: 1

$$(Y_i(0), Y_i(1)) \perp W_i | X_i$$

- Sometimes called “conditional independence assumption” or “selection on observables”.
- Can see this is implicit in the regression $Y_i = \alpha + \tau W_i + X'_i \beta + \epsilon_i$ where $\epsilon_i \perp X_i$ under the assumption of a constant treatment effect (otherwise this is not the same)

Assumption 2 (Overlap)

$$0 < Pr(W_i = 1 | X_i) < 1$$

How useful are these assumptions?

Imbens (2015) has a good discussion on this. Suggests following motivations:

- This is a natural starting point. Compare treatment and control units, after adjusting for observables. Need not be the last word!
- All comparisons involve comparing treated to untreated units. Absent RCT, its up to researcher to investigate which comparisons to emphasize
- Often specifying a model can clarify how sensible this is. Guido has a good example on costs in the paper.

Under these assumptions, can we just use regression?

- Let $\mu_w(x) = E[Y_i(w)|X_i = x]$
- A regression estimate of τ is then

$$\hat{\tau}_{reg} = \frac{1}{N} \sum_i W_i(Y_i - \hat{\mu}_0(X_i)) + (1 - W_i)(\hat{\mu}_1(X_i) - Y_i)$$

- Typically estimate

$$Y_i = \alpha + \beta' X_i + \tau W_i + \epsilon_i$$

which assumes $\mu_w(x) = \beta' x + \tau * w$

- Could easily also compute

$$\mu_w(x) = \alpha_w + \beta'_w x$$

- Key point is that this estimator can be viewed as a **missing data** problem, where predictions are computed using regression.

When is this likely to be a problem?

- Note $\mu_0(x)$ is used to predict the "missing" control outcomes for the treated observations.
- Want this prediction at the average treated covariates \bar{X}_T
- With linear regression, our average control prediction for the treated observations is going to be $\bar{Y}_C + \hat{\beta}'(\bar{X}_T - \bar{X}_C)$
- Ok if:
 - ① $\mu()$ is properly specified
 - ② treated and control observations are similar (in X)
- First condition is untestable, but in practice predictions are often sensitive to functional form
- Leads to a big emphasis on covariate balance.

Matching

- Regression imputes missing potential outcomes using regression.
- Matching imputes using the *realized* outcome of (nearly) identical units in the opposite assignment group.
- Remember, we're in a world where we've assumed unconfoundedness. Only challenge is that the treatment group and the control group don't have the same distribution of X 's.
- **Re-weight** the un-treated population so that it resembles the treated population.
- Once distribution of X_i is the same for both groups $X_i|W_i \sim X_i$ then we assume all other differences are irrelevant and can just compare means.

Matching

Let $F^1(x)$ be the distribution of characteristics in the treatment group, we can define the ATE as

$$\begin{aligned} E[Y(1) - Y(0)|T = 1] &= E_{F^1(x)}[E(Y(1) - Y(0)|T = 1, X)] \\ &= E_{F^1(x)}[E(Y(1)|T = 1, X)] - E_{F^1(x)}[E(Y(0)|T = 1, X)] \text{ linearity} \end{aligned}$$

The first part we observe directly:

$$= E_{F^1(x)}[E(Y(1)|T = 1, X)]$$

But the counterfactual mean is not observed!

$$= E_{F^1(x)}[E(Y(0)|T = 1, X)]$$

But conditional independence does this for us:

$$E_{F^1(x)}[E(Y(0)|T = 1, X)] = E_{F^1(x)}[E(Y(0)|T = 0, X)]$$

A Matching Example

Here is an example where matching was helpful from a paper by Prof. Mortimer:

- She ran a randomized experiment where we removed Snickers bars from around 60 vending machines in office buildings in downtown Chicago.
- There are a few possible control groups:
 - ① Same vending machine in other weeks (captures heterogeneous tastes in the cross section)
 - ② Other vending machines in the same week (might capture aggregate shocks, ad campaigns, etc.)
- We went with #1 as #2 was not particularly helpful.

A Matching Example

Major problem was that there was a ton of heterogeneity in the overall level of (potential) weekly sales which we call M_t .

- Main source of heterogeneity is how many people are in the office that week, or how late they work.
- Based on total sales our average over treatment weeks was in the 74th percentile of all weeks.
- This was after removing a product, so we know sales should have gone down!
- How do we fix this without running the experiment for an entire year!

References

A Matching Example

Ideally we could just observe M_t directly and use that as our matching variable X

- We didn't observe it directly and tried a few different measures:
 - Sales at the soda machine next to the snack machine
 - Sales of salty snacks at the same machine (not substitutes for candy bars).
 - We used k-NN with $k = 4$ to select control weeks – notice we re-weight so that overall sales are approximately same (minus the removed product).
- We also tried a more structured approach:
 - Define controls weeks as valid IFF
 - Overall sales were weakly lower
 - Overall sales were not less than Overall Sales less expected sales less Snickers Sales.

Notes: Control weeks are selected through the-neighbor matching using four control observations for each treatment week.
Percentiles are relative to the full distribution of control weeks.

How do you actually do this?

- One dimension is easy: just sort
- In multiple dimensions, there are a variety of built in nearest neighbor packages (Abadie Imbens (2006))
- What's nice about these is that the researcher only has to pick the number of matches (although the default tolerances not always innocuous)
- This is still cursed in that our nearest neighbors get further away as the dimension grows.
- Suppose instead we had a **sufficient statistic**

Propensity Score

- Rosenbaum and Rubin propose the **propensity score**

$$e(x) = \Pr(W_i = 1 | X_i) = E[W_i | X_i = x]$$

- They prove that under the assumption of unconfoundedness,

$$(Y_i(0), Y_i(1)) \perp W_i | e(X_i)$$

- So even if X is high dimensional, it is sufficient to condition on a scalar function
- Of course, the true propensity score is not known...

This suggests an attractive weighting

4.B.3 Propensity Score Estimators: Weighting

$$\mathbb{E}\left[\frac{WY}{e(X)}\right] = \mathbb{E}\left[\mathbb{E}\left[\frac{WY_i(1)}{e(X)} \middle| X\right]\right] = \mathbb{E}\left[\mathbb{E}\left[\frac{e(X)Y_i(1)}{e(X)}\right]\right] = \mathbb{E}[Y_i(1)],$$

and similarly

$$\mathbb{E}\left[\frac{(1-W)Y}{1-e(X)}\right] = \mathbb{E}[Y_i(0)],$$

implying

$$\tau_P = \mathbb{E}\left[\frac{W \cdot Y}{e(X)} - \frac{(1-W) \cdot Y}{1-e(X)}\right].$$

With the propensity score known one can directly implement this estimator as

$$\tilde{\tau} = \frac{1}{N} \sum_{i=1}^N \left(\frac{W_i \cdot Y_i}{e(X_i)} - \frac{(1-W_i) \cdot Y_i}{1-e(X_i)} \right). \quad (3)$$

Approaches now look similar

- One option is "inverse probability weighting"
- Nonparametrically estimate $e(x)$, then compute

$$\hat{\tau} = \sum_i^N \frac{W_i Y_i}{\hat{e}(X_i)} / \sum_i^N \frac{W_i}{\hat{e}(X_i)} - \sum_i^N \frac{(1 - W_i) Y_i}{1 - \hat{e}(X_i)} / \sum_i^N \frac{(1 - W_i)}{1 - \hat{e}(X_i)}$$

where this is slightly more complicated than just plugging in $\hat{e}()$ because in your sample the weights won't necessarily sum to one (Hirano, Imbens and Ridder (2003))

- Alternatively we could flexibly estimate μ_w then plug in these predictions for each observation manually.
- With discrete covariates, these will be equivalent!
- Otherwise there finite sample properties will vary depending on the smoothness of the regression and propensity score functions.

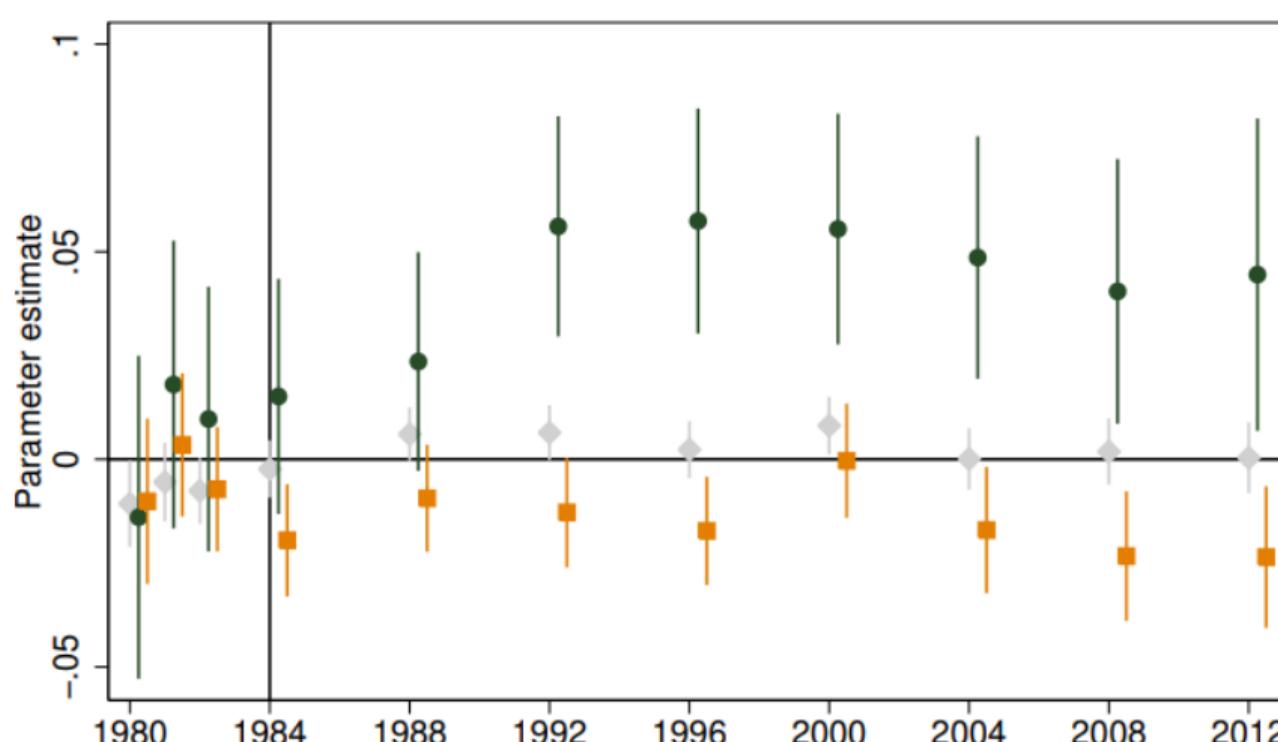

What about matching on the (estimated) propensity score?

- VERY widely used approach
- Large sample properties not known
- "Why Propensity Scores Should Not Be Used for Matching" ([King and Nielsen, Forthcoming](#))
- Show this performs poorly in simulations compared to matching on X's directly.
- One alternative from the same author's: Coarsened Exact Matching
 - Available in R and Stata from [Gary King's website](#)
 - The idea: temporarily coarsen each variable into substantively meaningful groups, exact match on these coarsened data, and then retain only the original (uncoarsened) values of the matched data.

CEM has many uses

- Linh To's JMP:
- Question: Is there a signal value to parental leave?
- Theory: many PBNE's. In practice depends on pooling.
- Setting: Extension of leave in Denmark.
- Look for response among three types of women:
 - ① pool, pool
 - ② pool, separate
 - ③ separate, separate
- Convincing RD: restrict to sample already pregnant when law announced
- Challenge: Only see mothers in one group or the other
- Solution: Match each pre period mother using their closest post-period counterpart, and assign her to that post-group.

(a) Log wages

What can ML add here?

- Estimating the propensity score is a pure **prediction** problem. We don't care what causes someone to be treated in this setup
- This is a natural place for ML (decision trees, random forests).
- What should we use to predict?

Some recent ML proposals I

Belloni, Chernozhukov, Fernández, and Hansen (2013)

- "double selection" procedure
- use LASSO to select X which predict Y , and another LASSO to find X that predict W
- then do OLS on the union of the two sets of covariates
- show this performs better than simple regularized regression of outcome on treatment and covariates in one step

Some recent ML proposals II

Athey, Imbens, and Wager (2016)

“Approximate Residual Balancing: De-Biased Inference of Average Treatment Effects in High Dimensions”

- Idea: In order to predict the counterfactual outcomes that the treatment group would have had in the absence of the treatment, it is necessary to extrapolate from control
- This is confounded by imbalance.
- AIW construct weights so these samples are equivalent, and run penalized regression to compute τ

Assessing Unconfoundedness

- This assumption is fundamentally untestable
- However people have proposed a number of tests which, if failed, might be *inconsistent* with unconfoundedness.
- One option is to look for an "effect" on an untreated group.
- Imagine you had one sample of "eligible" units, some who were treated and some who weren't. And another sample of "ineligible" units, all of whom are also untreated by construction.
- You could estimate a difference in outcomes within the two untreated groups. If eligible but untreated units look different than ineligible, that should be worrisome.
- Imbens lecture does this with the Lalonde data and the CPS.
- Another natural approach is to use "pseudo outcomes", like lagged Y.

Assessing Overlap

- Obviously want to start with a summary table comparing the means of your treatment and control groups.
- What's a big difference? t-stats reflective of sample size
- Instead report the normalized difference in covariates. According to Imbens, a an average difference bigger than 0.25 standard deviations is worrisome.
- Another alternative is to plot the propensity score for the two groups.

Matching wrapup

- Even under unconfoundedness, very important to ensure overlap
- Restrict your sample so that its balanced, using exact matching if low dimensional, coarse or propensity score otherwise
- Assess unconfoundedness using a psuedo-outcome if possible
- Run regression on your matched sample

Instrumental Variables

See Guido Imbens's [NBER Slides](#).

How Close to ATE?

Angrist and Imbens give some idea how close to the ATE the LATE is:

$$\widehat{\beta}_1^{TSLS} \xrightarrow{p} \frac{E[\beta_{1i}\pi_{1i}]}{E[\pi_{1i}]} = LATE$$

$$LATE = ATE + \frac{Cov(\beta_{1i}, \pi_{1i})}{E[\pi_{1i}]}$$

- Weighted average for people with large π_{1i} .
- Late is treatment effect for those whose probability of treatment is most influenced by Z_i .
- If you always (never) get treated you don't show up in LATE.

How Close to ATE?

- With different instruments you get different π_{1i} and TSLS estimators!
- Even with two valid Z_1, Z_2
 - Can be influential for different members of the population.
 - Using Z_1 , TSLS will estimate the treatment effect for people whose probability of treatment X is most influenced by Z_1
 - The LATE for Z_1 might differ from the LATE for Z_2

Example: Cardiac Catheterization

- Y_i = survival time (days) for AMI patients
- X_i = whether patient received cardiac catheterization (or not) (intensive treatment)
- Z_i = differential distance to CC hospital

$$\text{SurvivalDays}_i = \beta_0 + \beta_{1i} \text{CardCath}_i + u_i$$

$$\text{CardCath}_i = \pi_0 + \pi_{1i} \text{Distance}_i + v_i$$

- For whom does distance have the greatest effect on probability of treatment?
- For those patients what is their β_{1i} ?

Example: Cardiac Catheterization

- IV estimates causal effect for patients whose value of X_i is most heavily influenced by Z_i
 - Patients with small positive benefit from CC in the expert judgement of EMT will receive CC if trip to CC hospital is short (**compliers**)
 - Patients that need CC to survive will always get it (**always-takers**)
 - Patients for which CC would be unnecessarily risky or harmful will not receive it (**never-takers**)
 - Patients for who would have gotten CC if they lived further from CC hospital (hopefully don't see) (**defiers**)
- We mostly weight towards the people with small positive benefits.

Local Average Treatment Effect

So how is this useful?

- It shows why IV can be meaningless when effects are heterogeneous.
- It shows that if the monotonicity assumption can be justified, IV estimates the effect for a particular subset of the population.
- In general the estimates are specific to that instrument and are not generalisable to other contexts.
- As an example consider two alternative policies that can increase participation in higher education.
 - Free tuition is randomly allocated to young people to attend college ($Z_1 = 1$ means that the subsidy is available).
 - The possibility of a competitive scholarship is available for free tuition ($Z_1 = 1$ means that the individual is allowed to compete for the scholarship).

Local Average Treatment Effect

- Suppose the aim is to use these two policies to estimate the returns to college education. In this case, the pair $\{Y^1, Y^0\}$ are log earnings, the treatment is going to college, and the instrument is one of the two randomly allocated programs.
- First, we need to assume that no one who intended to go to college will be discouraged from doing so as a result of the policy (monotonicity).
- This could fail as a result of a General Equilibrium response of the policy; for example, if it is perceived that the returns to college decline as a result of the increased supply, those with better outside opportunities may drop out.

Local Average Treatment Effect

- Now compare the two instruments.
- The subsidy is likely to draw poorer liquidity constrained students into college but not necessarily those with the highest returns.
- The scholarship is likely to draw in the best students, who may also have higher returns.
- It is not a priori possible to believe that the two policies will identify the same parameter, or that one experiment will allow us to learn about the returns for a broader/different group of individuals.

Example: Pretrial Detention

- In US, innocent until proven guilty.
- Some defendants are detained prior to trial.
- Extreme cases are obvious, but lots of discretion in the middle.
- What are the impacts on:
 - time served
 - future crime
 - rehabilitation into workforce

Example: Pretrial Detention

The Effects of Pretrial Detention on Conviction, Future Crime, and Employment: Evidence from Randomly Assigned Judges[†]

By WILL DOBBIE, JACOB GOLDIN, AND CRYSTAL S. YANG*

Over 20 percent of prison and jail inmates in the United States are currently awaiting trial, but little is known about the impact of pretrial detention on defendants. This paper uses the detention tendencies of quasi-randomly assigned bail judges to estimate the causal effects of pretrial detention on subsequent defendant outcomes. Using data from administrative court and tax records, we find that pretrial detention significantly increases the probability of conviction, primarily through an increase in guilty pleas. Pretrial detention has no net effect on future crime, but decreases formal sector employment and the receipt of employment- and tax-related government benefits.

Means for detained vs released defendants

Interpretation: Who is marginal here?

Interpretation: Who is marginal here?

- Instrument isn't binary here
- Thought experiment is the same though: identify which defendants get out under the most lenient judge minus those that get out under the strictest judge

Table C.1: Sample Share by Compliance Type

Model Specification:	Local Linear Model			Linear Model		
	1%	1.5%	2%	1%	1.5%	2%
Leniency Cutoff:						
Compliers	0.13	0.13	0.13	0.11	0.10	0.09
Never Takers	0.36	0.36	0.36	0.39	0.39	0.40
Always Takers	0.51	0.51	0.51	0.50	0.51	0.51

Who are the compliers?

- Follow strategy of Dahl et al (QJE 2014)
- Estimate complier share by subgroup

Table C.2: Characteristics of Marginal Defendants

		$P[X = x]$	$P[X = x \text{complier}]$	$\frac{P[X=x \text{complier}]}{P[X=x]}$
	White	0.402 (0.001)	0.375 (0.017)	0.931 (0.042)
	Non-White	0.598 (0.001)	0.624 (0.017)	1.047 (0.028)
	Drug	0.274 (0.001)	0.301 (0.015)	1.099 (0.054)
	Non-Drug	0.726 (0.001)	0.699 (0.015)	0.963 (0.020)
	Violent	0.173 (0.001)	0.010 (0.012)	0.058 (0.068)
	Non-Violent	0.827 (0.001)	0.990 (0.012)	1.197 (0.014)

How useful is LATE here?

- What can you do with this estimate?
- Is it of policy importance?

Example: Dams

DAMS*

ESTHER DUFLO AND ROHINI PANDE

This paper studies the productivity and distributional effects of large irrigation dams in India. Our instrumental variable estimates exploit the fact that river gradient affects a district's suitability for dams. In districts located downstream from a dam, agricultural production increases, and vulnerability to rainfall shocks declines. In contrast, agricultural production shows an insignificant increase in the district where the dam is located but its volatility increases. Rural poverty declines in downstream districts but increases in the district where the dam is built, suggesting that neither markets nor state institutions have alleviated the adverse distributional impacts of dam construction.

Example: Dams

- What is the exclusion restriction here?
- How useful is this LATE?

Weak instruments

- So far we have assumed that the instrument is **relevant**

$$\text{cov}(Z, W) > 0$$

- Intuitively, if there are no “compliers”, we can’t learn anything from IV.
- In applications, instruments are sometimes barely relevant, i.e. $\hat{\text{Cov}}(dz, x) \neq 0$, but it’s close.
- This leads to:
 - Large finite sample bias of $\hat{\beta}^{2SLS}$
 - Inference issues: (wrong standard error, incorrect p-values, incorrect confidence intervals)

Setup:
$$Y_i = X_i\beta + \varepsilon_i \quad (\text{Structural equation}) \quad (1)$$

$$X_i = Z'_i \pi + V_i \quad (\text{First stage}) \quad (2)$$

$$Y_i = Z'_i \delta + U_i, \quad \delta = \pi\beta, \quad \varepsilon = U - \beta V. \quad (\text{Reduced form}) \quad (3)$$

The two conditions for instrument validity

- (i) Relevance: $\text{cov}(Z, X) \neq 0$ or $\pi \neq 0$ (general k)
- (ii) Exogeneity: $\text{cov}(Z, \varepsilon) = 0$

The IV estimator when $k = 1$ (Wright 1926)

$$\begin{aligned} \text{cov}(Z, Y) &= \text{cov}(Z, X\beta + \varepsilon) = \text{cov}(Z, X)\beta + \text{cov}(Z, \varepsilon) \\ &= \text{cov}(Z, X)\beta \quad \text{by (i)} \end{aligned}$$

so

$$\beta = \frac{\text{cov}(Z, Y)}{\text{cov}(Z, X)} \quad \text{by (ii)}$$

IV estimator:

$$\text{Setup: } Y_i = X_i\beta + \varepsilon_i \quad (\text{Structural equation}) \quad (1)$$

$$X_i = Z'_i\pi + V_i \quad (\text{First stage}) \quad (2)$$

$$Y_i = Z'_i\delta + U_i, \quad \delta = \pi\beta, \quad \varepsilon = U - \beta V. \quad (\text{Reduced form}) \quad (3)$$

$k > 1$: Two stage least squares (TSLS)

$$\hat{\beta}^{\text{TSLS}} = \frac{n^{-1} \sum_{i=1}^n \hat{X}_i Y_i}{n^{-1} \sum_{i=1}^n \hat{X}_i^2}, \quad \text{where } \hat{X}_i = \text{predicted value from first stage}$$

$$= \frac{\mathbf{X}' \mathbf{Z} (\mathbf{Z}' \mathbf{Z})^{-1} \mathbf{Z}' \mathbf{Y}}{\mathbf{X}' \mathbf{Z} (\mathbf{Z}' \mathbf{Z})^{-1} \mathbf{Z}' \mathbf{X}}$$

$$= \frac{\hat{\pi}' \hat{Q}_{ZZ} \hat{\delta}}{\hat{\pi}' \hat{Q}_{ZZ} \hat{\pi}}, \quad \text{where } \hat{Q}_{ZZ} = n^{-1} \sum_{i=1}^n Z_i Z'_i$$

The weak instruments problem is a “divide by zero” problem

- $\text{cov}(Z, X)$ is nearly zero; or π is nearly zero; or
- $\hat{\pi}' \hat{Q}_{ZZ} \hat{\pi}$ is noisy

Weak instruments

- This is an active area of research. See Angrist and Pischke (Ch. 4); or Stock and Andrews 2018 [NBER minicourse](#) for a recent treatment.
- Always report first stage F statistic for significance of coefficients on instruments - rule of thumb: $F \geq 10$ is okay (under weak instrument asymptotics, bias of 2SLS and is $< 10\%$ when $F \geq 10$.)
- In general, adding weak instruments makes it worse!
- Estimates approach OLS. If instrument doesn't satisfy exclusion restriction, this could be even worse!

LASSO for selecting instruments

- Data often gives us many plausibly relevant instruments that satisfy the exclusion restriction. Which should we use?
- We know that adding many weak instruments is problematic.
- Intuitively we want something this is highly *predictive* of the endogenous variable. This is what Lasso is good at. ([Belloni et al., 2012](#))

Application: Eminent Domain

- How do changes in the government's ability to appropriate property affect property markets?
- Challenge: Changes likely endogenous to the strength of those markets and other economic factors
- Even if law changes are endogenous, much of the real world variation comes from court rulings.
- Instrument: Judges

IV Challenge: Which judges are more inclined to rule for/ against eminent domain?

- Unlike pretrial detention example, don't have large N of other cases.
- Many judge characteristics: gender, race, religion, political affiliation, whether the judge's bachelor's degree was obtained in-state, whether the bachelor's degree is from a public university, whether the JD was obtained from a public university, and whether the judge was elevated from a district court.
- All are randomly assigned. Which ones are *relevant*?

How do we typically proceed here?

- Pick the ones that make the most sense on intuitive grounds.
- In another paper, Chen and Yeh do exactly this, using
 - ① whether a judge did not report a religious affiliation
 - ② whether the judge earned her law degree from a public institution
- Could try other instruments and see if results are "robust" (should they be?)
- Could try everything: data mining/ not feasible
- Belloni et al. create 140 first stage vars, and let LASSO decide.
- Since all satisfy the exclusion restriction (by assumption), this first stage selection has no bearing on second stage interpretation.

Regression Discontinuity Design

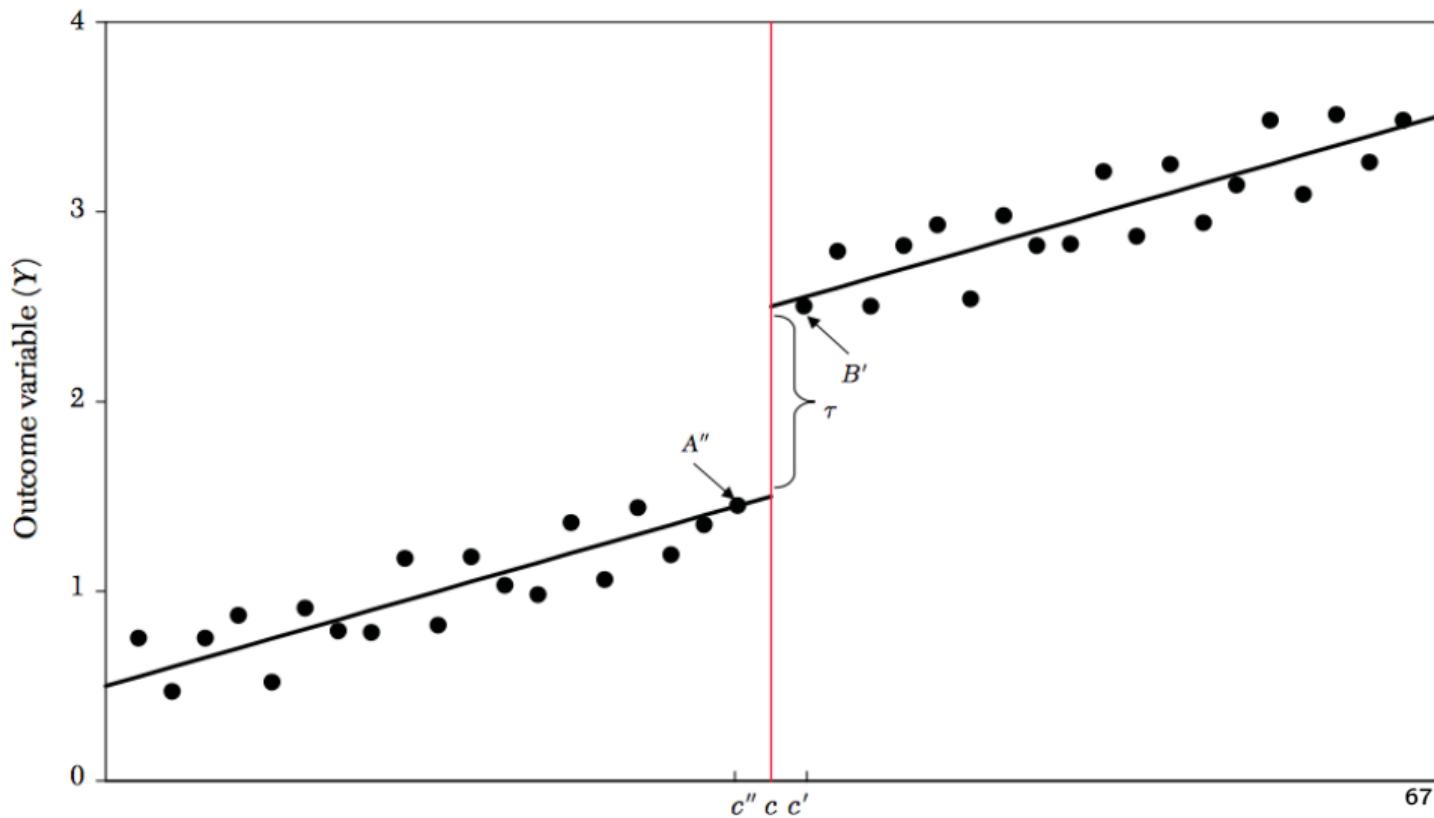

- Another popular research design is the **Regression Discontinuity Design**.
- In some sense this is a special case of IV regression. (RDD estimates a LATE).
- Most of Chris's slides taken from the JEL Paper by Lee and Lemieux (2010).
- For an extensive recent treatment, see "A Practical Introduction to Regression Discontinuity Designs" (Cattaneo, Idrobo and Titiunik (2019, CUP)) ([available here](#))
- Matias Cattaneo has a number of useful tools (in R and Stata) available on his [website](#).

- We have a **running or forcing variable** x such that

$$\lim_{x \rightarrow c^+} P(T_i | X_i = x) \neq \lim_{x \rightarrow c^-} P(T_i | X_i = x)$$

- The idea is that there is a **discontinuous jump** in the **probability of being treated**.
- For now we focus on the **sharp discontinuity**:
 $P(T_i | X_i \geq c) = 1$ and $P(T_i | X_i < c) = 0$
- There is no single x for which we observe treatment and control. (Compare to Propensity Score!).
- The most important assumption is that of **no manipulability** $\tau_i \perp D_i$ in some neighborhood of c .
- Example: a social program is available to people who earned less than \$25,000.
 - If we could compare people earning \$24,999 to people earning \$25,001 we would have as-if random assignment. (MAYBE)
 - But we might not have that many people...

RDD: In Pictures

RDD: Sharp RD Case

RDD uses a set of assumptions distinct from our LATE/IV assumptions. Instead it depends on **continuity**.

- We need that $E[Y^{(1)}|X]$ and $E[Y^{(0)}|X]$ both be continuous at $X = c$.
- People just to the left of c are a valid control for those just to the right of c .
- **This is not a testable assumption**
 - Typically draw pictures of *other* X 's at c
- Most basic approach is regression

$$Y_i = \beta_0 + \tau D_i + X_i \beta + \epsilon_i$$

where $D_i = \mathbf{1}[X_i > c]$

- This puts a lot of restrictions (linearity) on the relationship between Y and X .

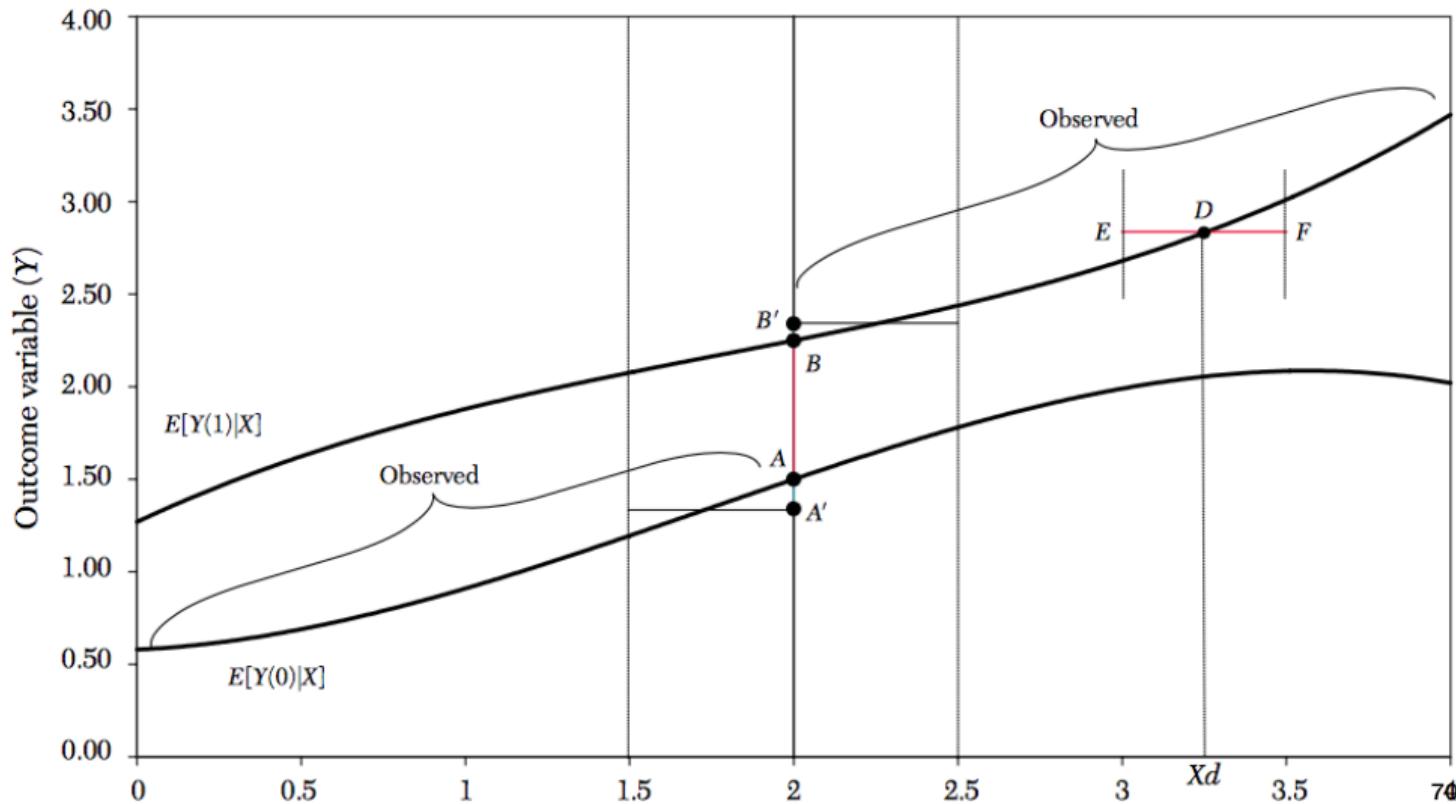

RDD: Nonlinearity

First thing to relax is assumption of linearity.

$$Y_i = f(x_i) + \tau D_i + \epsilon_i$$

- Two options for $f(x_i)$:
 - 1 Kernels: Local Linear Regression
 - 2 Polynomials: $Y_i = \beta_0 + \beta_1 x_i + \beta_2 x_i^2 + \cdots + \beta_p x_i^p + \tau D_i + \epsilon_i$.
 - Actually, people suggest different polynomials on each side of cutoff! (Interact everything with D_i).
- Same objective. Want to flexibly capture what happens on both sides of cutoff.
- Otherwise risk confusing nonlinearity with discontinuity!

RDD: Kernel Boundary Problem

Important reminder: LOCAL effect

Figure 4.1: RD Estimation with local polynomial

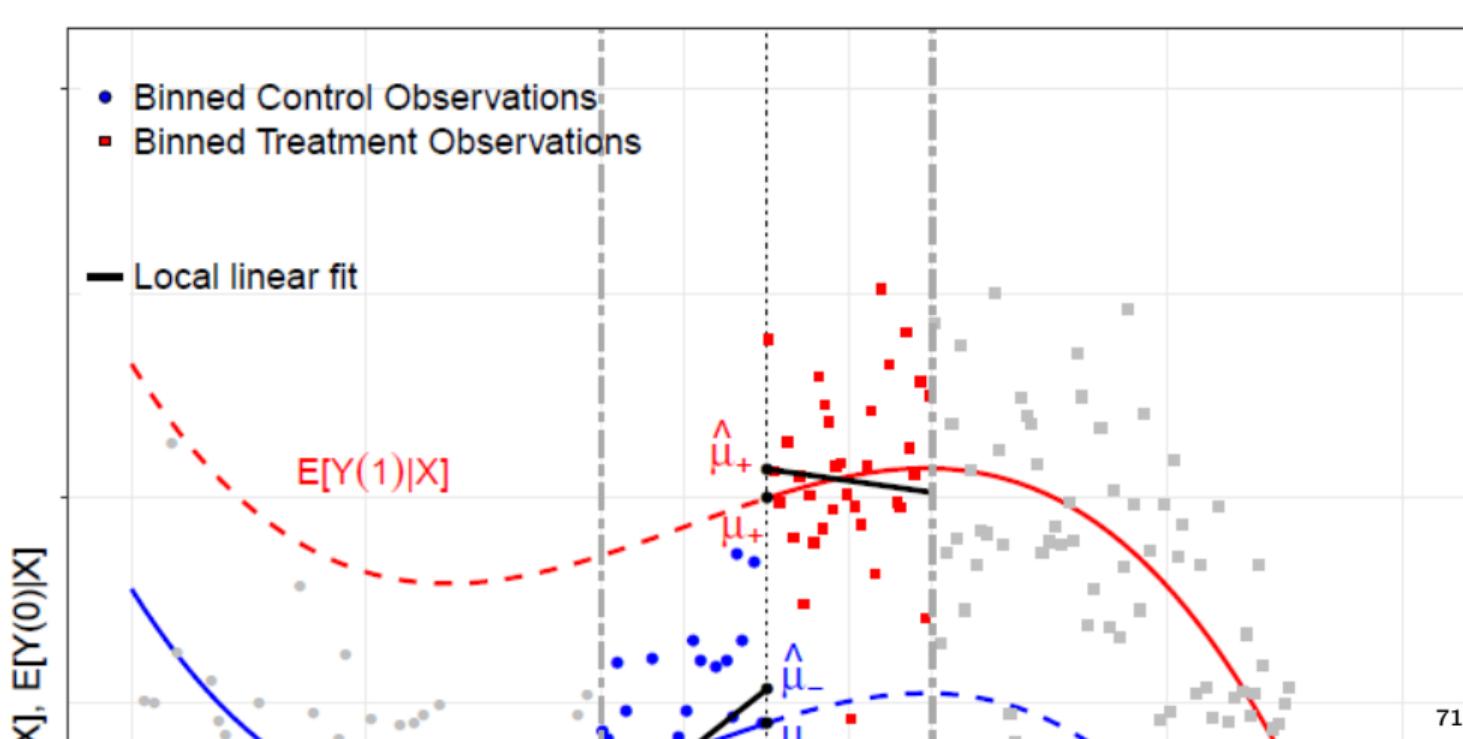

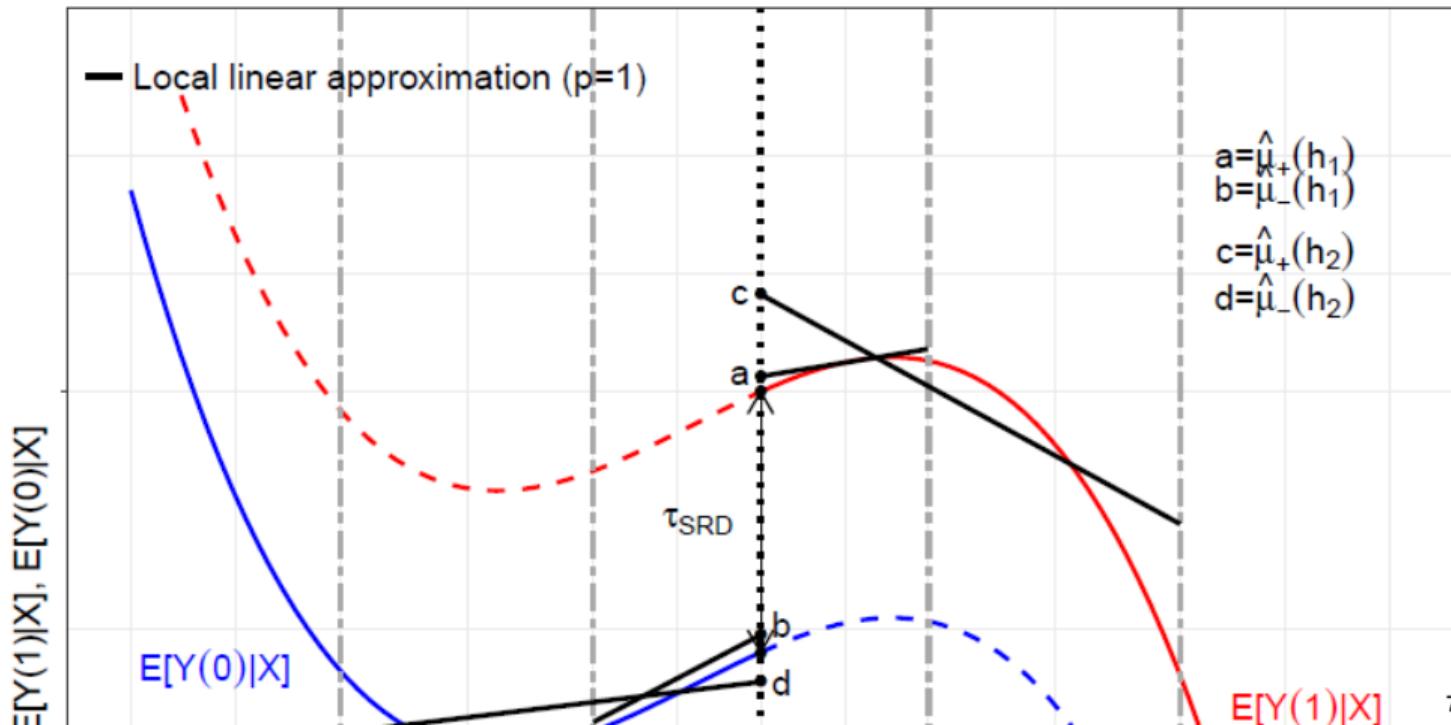

Figure 4.3: Bias in Local Approximations

RDD: Polynomial Implementation Details

To make life easier:

- replace $\tilde{x}_i = x_i - c$.
- Estimate coefficients $\beta: (1, \tilde{x}, \tilde{x}^2, \dots, \tilde{x}^p)$ and $\tilde{\beta}: (D_i, D_i\tilde{x}, D_i\tilde{x}^2, \dots, D_i\tilde{x}^p)$.
- Now treatment effect at c just the coefficient on D_i . (We can ignore the interaction terms).
- If we want treatment effect at $x_i > c$ then we have to account for interactions.
 - Identification away from c is somewhat dubious.
- Lee and Lemieux (2010) suggest estimating a coefficient on a dummy for each bin in the polynomial regression $\sum_k \phi_k B_k$.
 - Add polynomials until you can satisfy the test that the joint hypothesis test that $\phi_1 = \dots = \phi_k = 0$.
 - There are better ways to choose polynomial order...

RDD: Checklist

Most RDD papers follow the same formula (so should yours)

- Plot of $P(D|X)$ so that we can see the discontinuity
- Plot of $E[Y|X]$ so that we see discontinuity there also
- Plot of $E[W|X]$ so that we don't see a discontinuity in controls.
- Density of X (check for manipulation).
- Show robustness to different “windows”
- The OLS RDD estimates
- The Local Linear RDD estimates
- The polynomial (from each side) RDD estimates
- An f-test of “bins” showing that the polynomial is flexible enough.

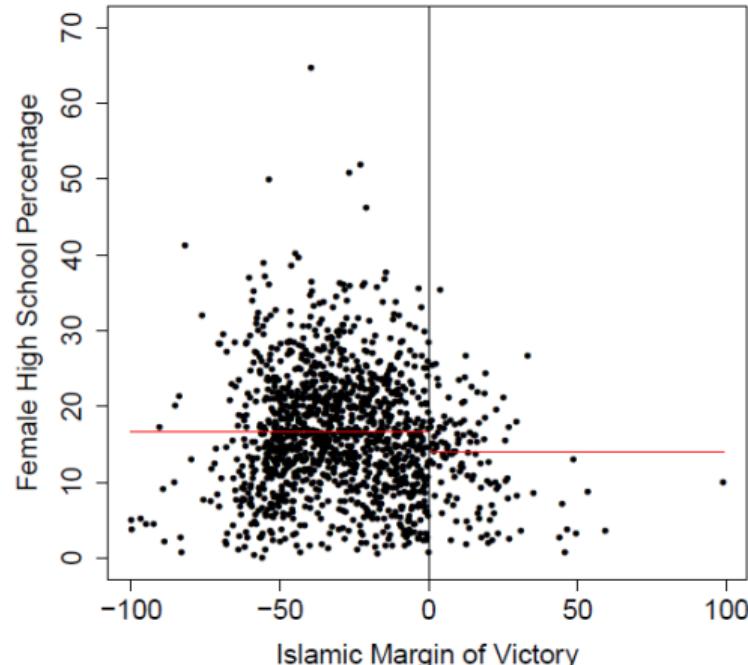

Read Lee and Lemieux (2010) before you get started.

Application: Meyersson (ECMA, 2014)

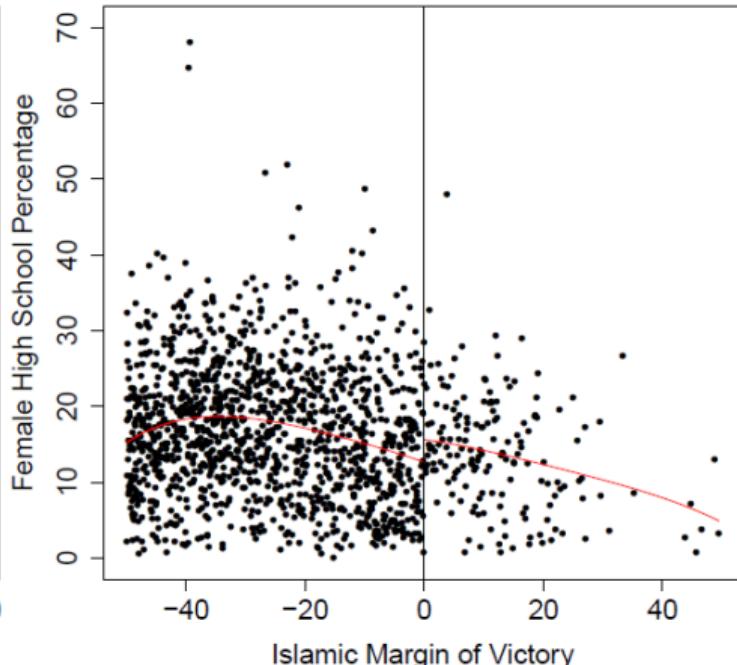

- RQ: Does Islamic political control affect women's empowerment?
- Challenge: Islamic rule endogenous
- Meyerson uses the Lee instrument on 1994 Turkish municipal elections
- Catteneo et al 2018 use this as a running example to demonstrate how to implement RD (and use their software)

How useful is this LATE?

How useful is this LATE?

Figure 2.4: Local Nature of RD Effect

(a) Mild Heterogeneity

(b) Severe Heterogeneity

Other Examples

Luca on Yelp

- Have data on restaurant revenues and yelp ratings.
- Yelp produces a yelp score (weighted average rating) to two decimals ie: 4.32.
- Score gets rounded to nearest half star
- Compare 4.24 to 4.26 to see the impact of an extra half star.
- Now there are multiple discontinuities: Pool them? Estimate multiple effects?

Fuzzy RD

An important extension in the Fuzzy RD. Back to where we started:

$$\lim_{x \rightarrow c^+} P(T_i | X_i = x) \neq \lim_{x \rightarrow c^-} P(T_i | X_i = x)$$

- We need a discontinuous jump in probability of treatment, but it doesn't need to be $0 \rightarrow 1$.

$$\tau_i(c) = \frac{\lim_{x \rightarrow c^+} P(Y_i | X_i = x) - \lim_{x \rightarrow c^-} P(Y_i | X_i = x)}{\lim_{x \rightarrow c^+} P(T_i | X_i = x) - \lim_{x \rightarrow c^-} P(T_i | X_i = x)}$$

- Under sharp RD everyone was a **complier**, now we have some **always takers** and some **never takers** too.
- Now we are estimating the treatment effect only for the population of compliers at $x = c$.
- This should start to look familiar. We are going to do IV!

Related Idea: Kinks

A related idea is that of **kinks**.

- Instead of a discontinuous jump in the outcome there is a discontinuous jump in β_i on x_i .
- Often things like tax schedules or government benefits have a kinked pattern.

Difference in Differences

- Sometimes we may feel we can impose more structure on the problem.
- Suppose in particular that we can write the outcome equation as

$$Y_{it} = \alpha_i + d_t + \beta_i T_{it} + u_{it}$$

- In the above we have now introduced a time dimension $t = \{1, 2\}$.
- Now suppose that $T_{i1} = 0$ for all i and $T_{i2} = 1$ for a well defined group of individuals in our population.
- This framework allows us to identify the ATT effect under the assumption that the growth of the outcome in the non-treatment state is independent of treatment allocation:

$$E[Y_{i2}^0 - Y_{i1}^0 | T] = E[Y_{i2}^0 - Y_{i1}^0]$$

- This is known as **parallel trends**.

Before and After

An even simpler estimator is the **event study**.

- We look at an outcome before or after an event
 - A news event: the announcement of a merger or stock split.
 - A tax change, a new law, etc.

$$\begin{aligned} E[Y_{i2} - Y_{i1}|T_{i2} = 1] &= E[Y_{i2}^1 - Y_{i1}^1|T_{i2} = 1] \\ &= d_2 - d_1 + E[\beta_i|T_{i2} = 1] \end{aligned}$$

- Except under strong conditions $d_2 = d_1$ we shouldn't believe the results of the before and after estimator.
- Main Problem: we attribute changes to treatment that might have happened anyway **trend**.
- e.g: Cigarette consumption drops 4% after a tax hike. (But it dropped 3% the previous four years).
- Also worry about: **anticipation**, **gradual rollout**, etc.

Treatment Effects

Difference in Differences

Let's try and estimate $d_2 - d_1$ directly and then difference it out. Here we use **parallel trends**:

$$E[Y_{i2}^0 - Y_{i1}^0 | T_{i2} = 1] = E[Y_{i2}^0 - Y_{i1}^0 | T_{i2} = 0]$$

$$E[Y_{i2} - Y_{i1} | T_{i2} = 0] = d_2 - d_1$$

We now obtain an estimator for ATT:

$$E[\beta_i | T_{i2} = 1] = E[Y_{i2} - Y_{i1} | T_{i2} = 1] - E[Y_{i2} - Y_{i1} | T_{i2} = 0]$$

which can be estimated by the difference in the growth between the treatment and the control group.

Parallel trends solves a "missing data" problem

Example: Minimum Wage

Minimum Wages and Employment: A Case Study of the Fast-Food Industry in New Jersey and Pennsylvania

By DAVID CARD AND ALAN B. KRUEGER*

On April 1, 1992, New Jersey's minimum wage rose from \$4.25 to \$5.05 per hour. To evaluate the impact of the law we surveyed 410 fast-food restaurants in New Jersey and eastern Pennsylvania before and after the rise. Comparisons of employment growth at stores in New Jersey and Pennsylvania (where the minimum wage was constant) provide simple estimates of the effect of the higher minimum wage. We also compare employment changes at stores in New Jersey that were initially paying high wages (above \$5) to the changes at lower-wage stores. We find no indication that the rise in the minimum wage reduced employment. (JEL J30, J23)

Example: Minimum Wage

5. Change in mean FTE employment, setting FTE at temporarily closed stores to 0 ^d	-2.28 (1.25)	0.23 (0.49)	2.51 (1.35)	0.90 (0.87)	0.49 (0.69)	-2.39 (1.02)	3.29 (1.34)	2.88 (1.23)

Notes: Standard errors are shown in parentheses. The sample consists of all stores with available data on employment. FTE (full-time-equivalent) employment counts each part-time worker as half a full-time worker. Employment at six closed stores is set to zero. Employment at four temporarily closed stores is treated as missing.

^a Stores in New Jersey were classified by whether starting wage in wave 1 equals \$4.25 per hour ($N = 101$), is between \$4.26 and \$4.99 per hour ($N = 140$), or is \$5.00 per hour or higher ($N = 73$).

^b Difference in employment between low-wage (\$4.25 per hour) and high-wage ($\geq \$5.00$ per hour) stores; and difference in employment between midrange (\$4.26–\$4.99 per hour) and high-wage stores.

^c Subset of stores with available employment data in wave 1 and wave 2.

^d In this row only, wave-2 employment at four temporarily closed stores is set to 0. Employment changes are based on the

Difference in Differences

Now consider the following problem:

- Suppose we wish to evaluate a training program for those with low earnings. Let the threshold for eligibility be B .
- We have a panel of individuals and those with low earnings qualify for training, forming the treatment group.
- Those with higher earnings form the control group.
- Now the low earning group is low for two reasons
 - ① They have low permanent earnings (α_i is low) - this is accounted for by diff in diff.
 - ② They have a negative transitory shock (u_{i1} is low) - this is not accounted for by diff in diff.
- #2 above violates the assumption $E[Y_{i2}^0 - Y_{i1}^0 | T] = E[Y_{i2}^0 - Y_{i1}^0]$.
- This is effectively regression to the mean: those unlucky enough to have a bad shock recover and show greater growth relative to those with a good shock. The nature of the bias depends on the stochastic properties of the shocks and how individuals select into training.

Who gets treated?

- The assumption on growth of the non-treatment outcome being independent of assignment to treatment may be violated, but it may still be true conditional on X .
- Consider the assumption

$$E[Y_{i2}^0 - Y_{i1}^0 | X, T] = E[Y_{i2}^0 - Y_{i1}^0 | X]$$

- This is just matching assumption on a redefined variable, namely the growth in the outcomes. In its simplest form the approach is implemented by running the regression

$$Y_{it} = \alpha_i + d_t + \beta_i T_{it} + \gamma'_t X_i + u_{it}$$

which allows for differential trends in the non-treatment growth depending on X_i . More generally one can implement propensity score matching on the growth of outcome variable when panel data is available.

DiD with Repeated Cross Sections

- Suppose we do not have available panel data but just a random sample from the relevant population in a pre-treatment and a post-treatment period.
- First consider a simple case where $E[Y_{i2}^0 - Y_{i1}^0 | T] = E[Y_{i2}^0 - Y_{i1}^0]$.
- We need to modify slightly the assumption to

$$\begin{aligned}E[Y_{i2}^0 | \text{Group receiving training}] - E[Y_{i1}^0 | \text{Group receiving training in the next period}] \\= E[Y_{i2}^0 - Y_{i1}^0]\end{aligned}$$

which requires additional assumption that the population we will be sampling from does not change composition.

- We can then obtain immediately an estimator for ATT as

$$\begin{aligned}E[\beta_i | T_{i2} = 1] \\= E[Y_{i2} | \text{Group receiving training}] - E[Y_{i1} | \text{Group receiving training next period}] \\- \{E[Y_{i2} | \text{Non-trainees}] - E[Y_{i1} | \text{Group not receiving training next period}]\}\end{aligned}$$

Difference in Differences with Repeated Cross Sections

- More generally we need an assumption of conditional independence of the form

$$\begin{aligned} E[Y_{i2}^0 | X, \text{Group receiving training}] - E[Y_{i1}^0 | X, \text{Group receiving training next period}] \\ = E[Y_{i2}^0 | X] - E[Y_{i1}^0 | X] \end{aligned}$$

- Under this assumption (and some auxiliary parametric assumptions) we can obtain an estimate of the effect of treatment on the treated by the regression

$$Y_{it} = \alpha_g + d_t + \beta T_{it} + \gamma' X_{it} + u_{it}$$

Difference in Differences with Repeated Cross Sections

- More generally we can first run the regression

$$Y_{it} = \alpha_g + d_t + \beta(X_{it})T_{it} + \gamma'X_{it} + u_{it}$$

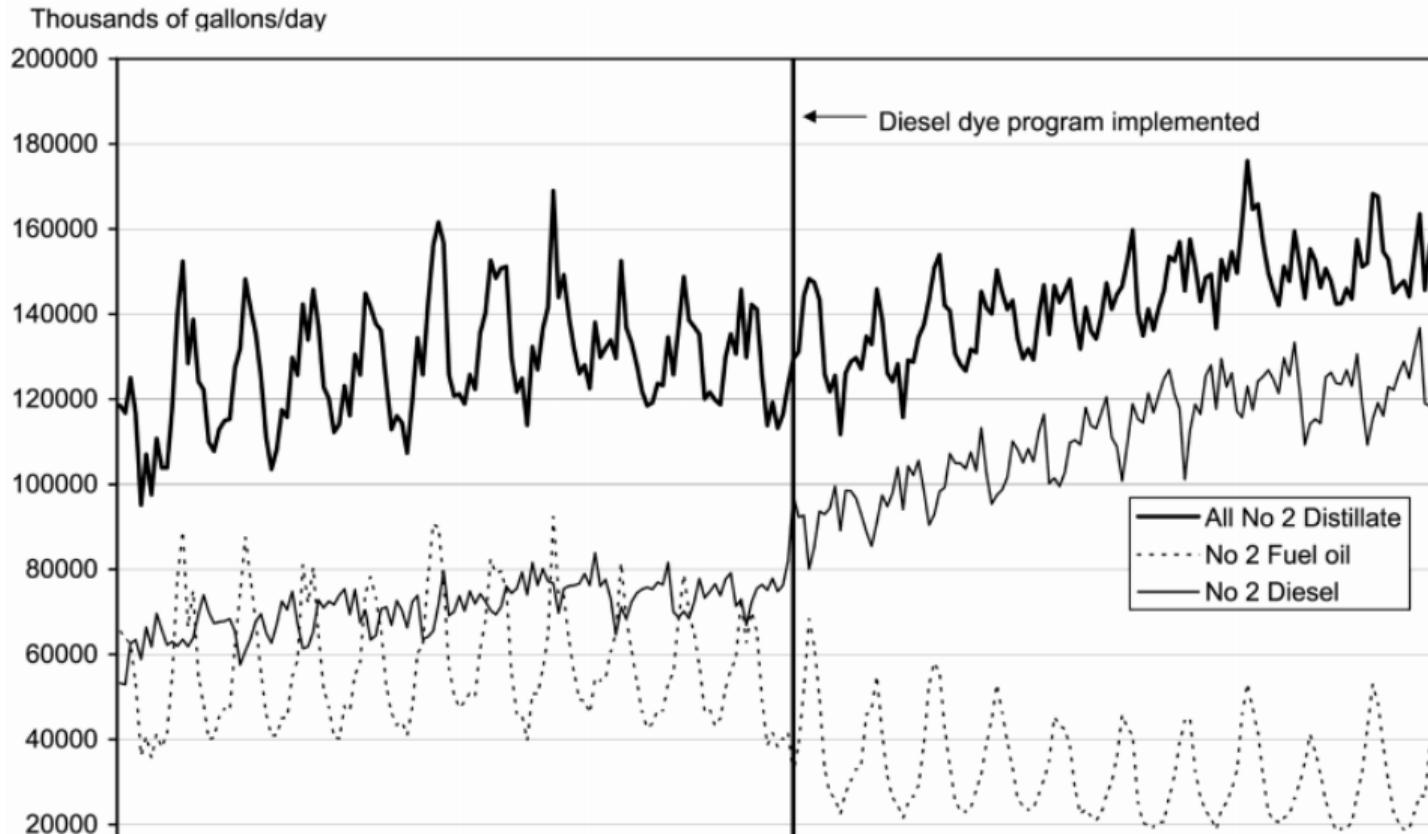

where α_g is a dummy for the treatment of comparison group, and $\beta(X_{it})$ can be parameterized as $\beta(X_{it}) = \beta'X_{it}$. The ATT can then be estimated as the average of $\beta'X_{it}$ over the (empirical) distribution of X .

- A non parametric alternative is offered by Blundell, Dias, Meghir and van Reenen (2004).

DiD vs Fixed Effects

- What if we have a long panel with many similar changes?
 - Greenstone (2002): Counties move in and out of Clean Air Act
 - Evans, Ringel, and Stech (1999): Since 1975, more than 200 state cigarette tax changes
- Fixed effects generalize DD with $T > 2$ periods and $J > 2$ groups
- Advantage relative to DD: more precise estimates by pooling several changes
- Disadvantage: fixed effects is a black-box regression, more difficult to check trends non-parametrically as with a single change

The best DiD's can be seen graphically

What about triple differencing?

- Sometime we might use a "placebo" DD to make parallel trends more convincing
- Example: Imagine a policy which offered STEM outreach to high school girls in Massachusetts
 - Natural DiD control group: boys in MA
 - However over time there could be general shifts in the relative outcomes of boys and girls everywhere
 - Suggest looking at how the difference between boys and girls in MA changed relative to the changes in other states (say RI)
- Logically sound, but much harder to see/ validate visually

Difference in Differences and Selection on Unobservables

- Suppose we relax the assumption of *no selection* on unobservables.
- Instead we can start by assuming that

$$E[Y_{i2}^0|X, Z] - E[Y_{i1}^0|X, Z] = E[Y_{i2}^0|X] - E[Y_{i1}^0|X]$$

where Z is an instrument which determines training eligibility say but does not determine outcomes in the non-training state. Take Z as binary (1,0).

- Non-Compliance: not all members of the eligible group ($Z = 1$) will take up training and some of those ineligible ($Z = 0$) may obtain training by other means.
- A difference in differences approach based on grouping by Z will estimate the impact of being allocated to the eligible group, but not the impact of training itself.

Difference in Differences and Selection on Unobservables

- Now suppose we still wish to estimate the impact of training on those being trained (rather than just the effect of being eligible)
- This becomes an IV problem and following up from the discussion of LATE we need stronger assumptions
 - Independence: for $Z = a$, $\{Y_{i2}^0 - Y_{i1}^0, Y_{i2}^1 - Y_{i1}^1, T(Z = a)\}$ is independent of Z .
 - Monotonicity $T_i(1) \geq T_i(0) \forall i$
- In this case LATE is defined by

$$[E(\Delta Y|Z = 1) - E(\Delta Y|Z = 0)]/[Pr(T(1) = 1) - Pr(T(0) = 1)]$$

assuming that the probability of training in the first period is zero.

Synthetic Controls

- DiD methods compare two groups before and after some change.
- Challenge: What's a good comparison group? Even if you pick the best available option, might not track each other that closely even in the pre-period.
- Moreover, if we don't have another untreated group that is well balanced against the treatment group, are we stuck?
- Synthetic control methods pick weighted averages from control population to construct better comparisons ([Abadie and Gardeazabal, 2003](#); [Abadie, Diamond, and Hainmueller, 2010](#))
- [Athey and Imbens \(2017\)](#) call this “arguably the most important innovation in the policy evaluation literature in the past 15 years”.

Initial motivation: Case studies

- Often we're interested in the aggregate effects of large, singular policies.
 - What was the impact of MassHealth?
 - Fukushima
 - Terrorism
 - German Re-unification
- What would a rigorous "case study" of these look like?

- Consider a panel with $J + 1$ units observed for $t = 1, 2, \dots, T$ periods.
- Unit 1 exposed to treatment in period T_0 (continues to T)
- Synthetic control estimator is

$$\hat{\alpha}_{1t} = Y_{1t} - \sum_{j=2}^{J+1} w_j^* Y_{jt}$$

where w is a collection of weights.

- In [Abadie, Diamond, and Hainmueller \(2010\)](#) the (non-negative) weights are chosen to minimize the distance between some chosen vector of preintervention characteristics (and sum to one).
- Subsequent literature has relaxed these.

ADH Example: CA Prop 99

- Anti cigarette law in CA in 1988
 - increased state excise tax by 25 cents per pack
 - earmarked the tax revenues to health and anti-smoking education budgets
 - funded anti-smoking media campaigns
 - spurred local clean indoor-air ordinances throughout the state
- What was the net effect on sales?

Delaware	0	New York	–
District of Columbia	–	North Carolina	0
Florida	–	North Dakota	0
Georgia	0	Ohio	0
Hawaii	–	Oklahoma	0
Idaho	0	Oregon	–
Illinois	0	Pennsylvania	0
Indiana	0	Rhode Island	0
Iowa	0	South Carolina	0
Kansas	0	South Dakota	0
Kentucky	0	Tennessee	0
Louisiana	0	Texas	0
Maine	0	Utah	0.334
Maryland	–	Vermont	0
Massachusetts	–	Virginia	0
Michigan	–	Washington	–
Minnesota	0	West Virginia	0
Mississippi	0	Wisconsin	0
Missouri	0	Wyoming	0

Table 1. Cigarette sales predictor means

Variables	California		Average of 38 control states
	Real	Synthetic	
Ln(GDP per capita)	10.08	9.86	9.86
Percent aged 15–24	17.40	17.40	17.29
Retail price	89.42	89.41	87.27
Beer consumption per capita	24.28	24.20	23.75
Cigarette sales per capita 1988	90.10	91.62	114.20
Cigarette sales per capita 1980	120.20	120.43	136.58
Cigarette sales per capita 1975	127.10	126.99	132.81

NOTE: All variables except lagged cigarette sales are averaged for the 1980–1988 period (beer consumption is averaged 1984–1988). GDP per capita is measured in 1997 dollars, retail prices are measured in cents, beer consumption is measured in gallons, and cigarette sales are measured in cents.

Parallel trends achieved by construction

What about inference

- SE's typically reported reflect uncertainty in sample relative to aggregate population.
- ADH propose using a placebo test to assess null of no change in CA.
- Steps:
 - ① Randomly select one of the other J control units / time cutoffs and declare it treated.
 - ② Construct synthetic controls and estimate ATT.
 - ③ Repeat many times
- Since none of these units are actually treated, this test distribution simulates distribution of the differences relative to the synthetic control under the true null of no effect.

A synthesis of approaches

- [Doudchenko and Imbens \(2016\)](#) attempt to synthesize several of the approaches discussed so far balancing (matching), regression, DiD, synthetic controls.
- These methods can be recast as trying to impute the untreated outcome for treated unit 0 to estimate $\hat{\tau}_{0,T} = Y_{0,T}(1) - \hat{Y}_{0,T}(0)$
- many impose the linear structure

$$\hat{Y}_{0,T}(0) = \mu + \sum_i^N w_i \dot{Y}_{i,T}^{obs}$$

Di consider a series of constraints

- ① no intercept: $\mu = 0$
- ② adding up: $\sum_i^N w_i = 1$
- ③ non-negativity: $w_i > 0$
- ④ exact balancing: $Y_{t,pre}^{obs} = \mu + w^T \mathbf{Y}_{c,pre}^{obs}$
- ⑤ constant weights: $w_i = \bar{w}$

- Assumptions 1-3 are imposed by ADH
- No intercept actually precludes defining feature of DiD
- Constant weights implicit when number of control units is large
- Other useful features of an objective function:
 - match pre period *outcomes* well
 - small number of features
 - non-disperse set of parameters
- All of these generally suggest regularization.

this paper. These five estimators include the original ADH estimator, the constrained estimator with the same restrictions, $\mu = 0$, $\sum_{i=1}^N \omega_i = 1$ and $\omega_i \geq 0$, the best subset estimator, and DID estimator, and the elastic net estimator. For the best subset estimator the optimal number of controls, based on cross-validation, is 1. For the elastic net estimator the tuning parameters, chosen by cross-validation, are $\alpha = 0.1$ and $\lambda = 45.5$, leading to 8 states with non-zero weights, all of them positive.

Table 1: California: Parameters

Model	$\sum_i w_i$	α
Original synth.	1	0
Constrained reg.	1	0
Elastic net	0.55	18.5
Best subset	0.32	37.6
Diff-in-diff	1	-14.4

Treatment effect heterogeneity

- Consider a binary treatment T_i
- Potential outcomes

$$Y_{0i} = \mu_0(X_i) + U_{0i}$$

$$Y_{1i} = \mu_1(X_i) + U_{1i}$$

- $\mu_j(x)$ represents the average outcome for individuals with observables x , and conditional mean zero U_{ji} captures unobserved heterogeneity (assumed to be additively separable)
- Individual treatment effect $\tau_i = Y_{1i} - Y_{0i}$
- ATE averages τ_i over entire population.
- ATT / ATU averages over those who received / didn't receive the treatment (somehow)
- LATE averages for those induced to switch due to an instrument

One quantity to rule them all: MTE

Their approach is known as the **marginal treatment effect** or MTE

- Heckman and Vytlacil (2005) provide a unifying non-parametric framework to categorize all of these effects
- Key insight is that those are all averages over different margins.
- Define the **marginal treatment effect** as the average treatment effect at the margin. The MTE isn't a number it is a **function**.
- All of the other objects (LATE, ATE, ATT, etc.) can be written as integrals (weighted averages) of the MTE.
- The idea is to bridge the treatment effect parameters (stuff we get from running regressions) and the structural parameters: features of $f(\tau_i)$.

Setup: Selection into treatment

Consider the latent variable discrete choice problem

- Decision utility

$$T_i^* = \mu_T(X_i, Z_i) - V_i$$

depends on at least one instrument Z which does not affect potential outcomes.

- V_i represents the unobserved disutility of decision.
- $T_i = 1$ if $T_i^* \geq 0$

Example: Let τ_i be lifetime earnings with and without college.

- Costs of attending $C_i = w_0 + \gamma' z_i + v_i$
- Rational students attend if

$$\tau_i - [w_0 + \gamma' z_i + v_i] > 0$$

- If we could condition on marginal students,

$$v_i = \tau_i - [w_0 + \gamma' z_i]$$

we'd be able to pin down the treatment effect at a given Z_i

HV Roy Model

The model

Outcomes	Choice model
$Y_1 = \mu_1 + U_1 = \alpha + \bar{\beta} + U_1$	$D = \begin{cases} 1 & \text{if } D^* \geq 0, \\ 0 & \text{if } D^* < 0 \end{cases}$
$Y_0 = \mu_0 + U_0 = \alpha + U_0$	
General case	
$(U_1 - U_0) \not\perp\!\!\!\perp D$ $\text{ATE} \neq \text{TT} \neq \text{TUT}$	

The researcher observes (Y, D, C) .

$$Y = \alpha + \beta D + U_0 \text{ where } \beta = Y_1 - Y_0.$$

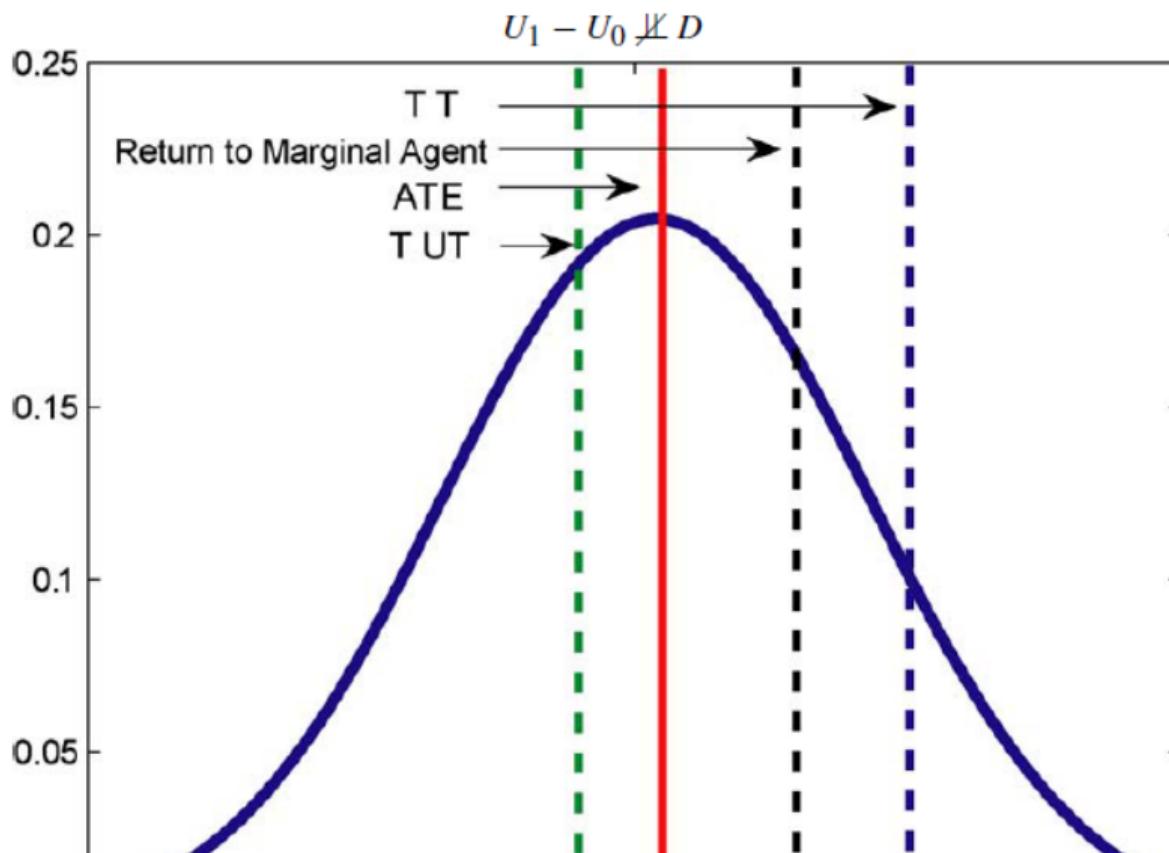

Parameterization

$$\alpha = 0.67, \quad (U_1, U_0) \sim N(\mathbf{0}, \Sigma), \quad D^* = Y_1 - Y_0 - C$$

$$\bar{\beta} = 0.2, \quad \Sigma = \begin{bmatrix} 1 & -0.9 \\ -0.9 & 1 \end{bmatrix}, \quad C = 1.5$$

Figure 1. Distribution of gains in the Roy economy. Source: Heckman, Urzua and Vytlacil (2006).

HV Roy Model

Propensity score

- Individuals select into treatment if the observable portion of their decision utility exceeds their unobserved resistance V_i
- Let F_V be the cdf of this resistance. Observed treatment thus implies

$$F_V(\mu_T(X_i, Z_i)) \geq F_V(V_i)$$

- As written, the LHS is just the **propensity score**: the probability of treatment based on observables.
- The RHS is simply individual i 's quantile of the unobserved distaste distribution. Let $u_{si} = F_V(V_i)$.
- So if an individual with a propensity score $P(X_i, Z_i) = p$ selects into treatment, it must be that that individual V_i is in the bottom p th percentile of the V distribution.

Think of the propensity score as an instrument

$P(T = 1|Z) = P(Z)$ works as our instrument with two assumptions:

- ① $(U_0, U_1, u_s) \perp P(Z)|X$. (Exogeneity)
- ② $P(Z|X)$ continuous support – ie conditional on X there is enough variation in Z for $P(Z)$ to take on all values $\in (0, 1)$.
 - This is much stronger than typical **relevance** condition.

MTE: Derivation

For simplicity write

$$\begin{aligned} Y_{0i} &= \gamma_0' X_i + U_{0i} \\ Y_{1i} &= \gamma_1' X_i + U_{1i} \end{aligned}$$

For any individual we observe

$$Y_i = \gamma_0' X_i + T_i(\gamma_1 - \gamma_0)' X_i + U_{0i} + T_i(U_{1i} - U_{0i})$$

MTE: Derivation

For simplicity write

$$\begin{aligned} Y_{0i} &= \gamma_0' X_i + U_{0i} \\ Y_{1i} &= \gamma_1' X_i + U_{1i} \end{aligned}$$

For any individual we observe

$$Y_i = \gamma_0' X_i + T_i(\gamma_1 - \gamma_0)' X_i + U_{0i} + T_i(U_{1i} - U_{0i})$$

Take the expectation conditional on x and the instrument

$$\begin{aligned} E[Y|X, P(Z) = p] &= \gamma_0' X + p(\gamma_1 - \gamma_0)' X \\ &\quad + E[T(U_1 - U_0)|X, P(Z) = p] \end{aligned}$$

MTE: Derivation

Note that $T = 1$ over the interval $u_s = [0, p]$ and zero for higher values of u_s .

$$E[T(U_1 - U_0)|P(Z) = p, X] =$$

$$\int_{-\infty}^{\infty} \int_0^p (U_1 - U_0) f((U_1 - U_0)|U_s = u_s) du_s d(U_1 - U_0)$$

Let $U_1 - U_0 \equiv \eta$.

$$E[T(\eta)|P(Z) = p, X] = \int_{-\infty}^{\infty} \int_0^p \eta f(\eta|U_s = u_s) d\eta du_s$$

MTE: Derivation

Can now express the MTE as

$$\begin{aligned}\Delta^{MTE}(p) &= \frac{\partial E[Y|X, P(Z) = p]}{\partial p} \\ &= (\gamma_1 - \gamma_0)' X + \int_{-\infty}^{\infty} \eta f(\eta|U_s = p) d\eta \\ &= (\gamma_1 - \gamma_0)' X + E[\eta|u_s = p]\end{aligned}$$

What is $E[\eta|u_s = p]$? The expected unobserved gain from treatment of those people who are on the treatment/no-treatment margin $P(Z) = p$.

How to Estimate an MTE

- ① Estimate $P(Z) = Pr(T = 1|Z)$ nonparametrically (include exogenous part of X in Z).
- ② Nonparametric regression of Y on X and $P(Z)$
- ③ For example,

$$E[Y|X, P(Z)p] = \gamma_0'X + \hat{p}(\gamma_1 - \gamma_0)'X + \kappa(\hat{p})$$

where $\kappa()$ is some nonlinear function (polynomials?)

- ④ Differentiate w.r.t. $P(Z)$
- ⑤ plot it for all values of $P(Z) = p$.

So long as $P(Z)$ covers $(0, 1)$ then we can trace out the full distribution of $\Delta^{MTE}(p)$.

MTE

References

Can now define any average we want in terms of
MTE

Calculate the outcome given (X, Z) (actually X and $P(Z) = p$).

ATE : This one is obvious. We treat everyone!

$$\int_{-\infty}^{\infty} \Delta^{MTE}(p) = (\gamma_1 - \gamma_0)' X + \underbrace{\int_{-\infty}^{\infty} E(\eta|u_s) d u_s}_0$$

What about LATE?

- LATE: Fix an X and $P(Z)$
- Consider a policy which varies probability of treatment for X from $b(X)$ to $a(X)$ with $a > b$.
- LATE integrates over the compliers with $b(X) \leq u_s \leq a(X)$.

$$\begin{aligned} LATE(X) &= \int_{-\infty}^{\infty} \Delta^{MTE}(p) \\ &= (\gamma_1 - \gamma_0)' X + \frac{1}{a(X) - b(X)} \int_{b(X)}^{a(X)} E(\eta|u_s) d u_s \end{aligned}$$

- One thing to note is that obviously LATE depends on the margin the policy shifts

How does this compare to IV?

[Some of what follows comes from [Cornelissen et al. \(2016\)](#)]

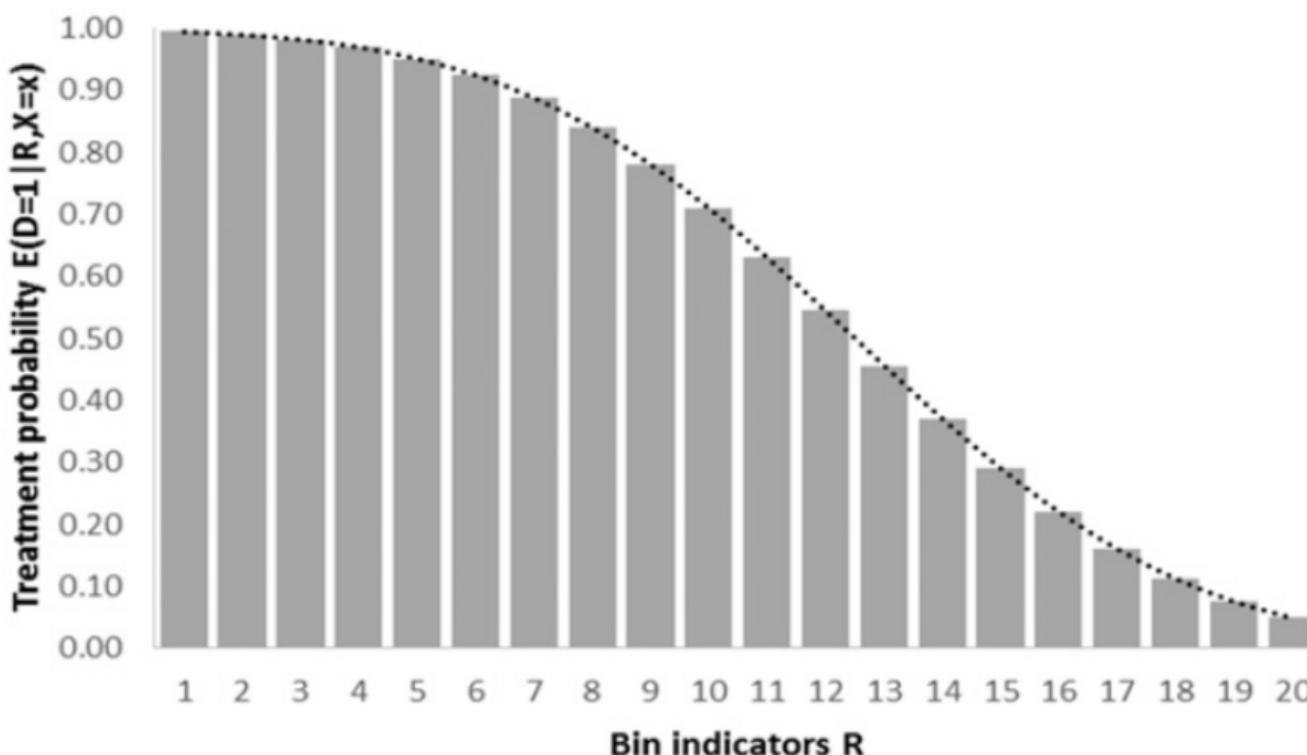

- Consider the Wald estimator with two points from a continuous instrument

$$Wald(z, z', x) = \frac{E[Y_i|Z_i = z, X_i = x] - E[Y_i|Z_i = z', X_i = x]}{E[T_i|Z_i = z, X_i = x] - E[T_i|Z_i = z', X_i = x]}$$

- We showed this recovers

$$\begin{aligned} LATE(z, z', x) &= E[\tau_i | T_{iz} > T_{iz'}, X_i = x] \\ &= E[\tau_i | P(z') < u_s < P(z), X_i = x] \end{aligned}$$

Consider a discretization of treatment probability distribution

Grouped IV averages relationship across bins

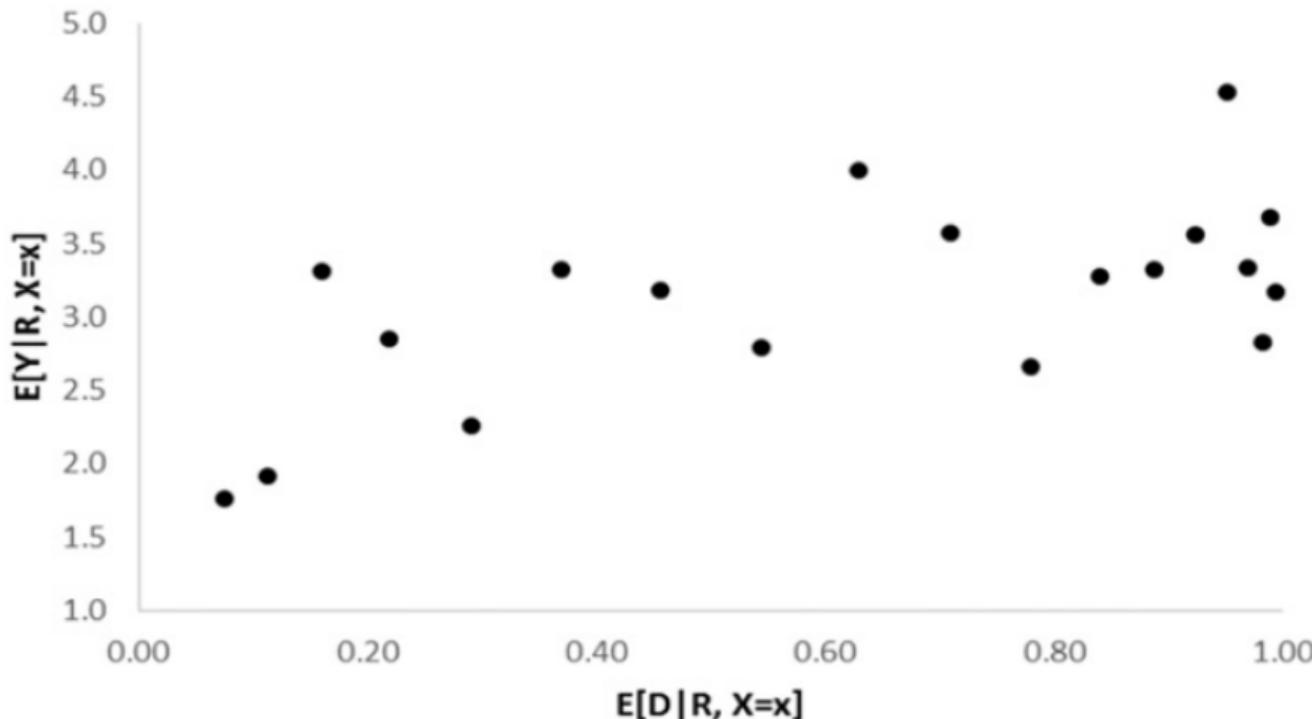

Fig. 3. Grouped data IV. Notes: Based on hypothetical data, the figure plots the average 135 / 159

How does this compare to IV?

- 2SLS is going to fit a line through these heterogenous effects, and aggregate IV will be the slope.
- MTE allows slope to vary across very fine bins
- Looking at the Wald formula, can see that MTE for a given u_s is the limit of LATE as $P(z') \rightarrow P(z)$
- Thus the MTE is actually identified from local IV (LIV) using small departures from propensity score at $u_s = P(z)$

Policy Relevant TE

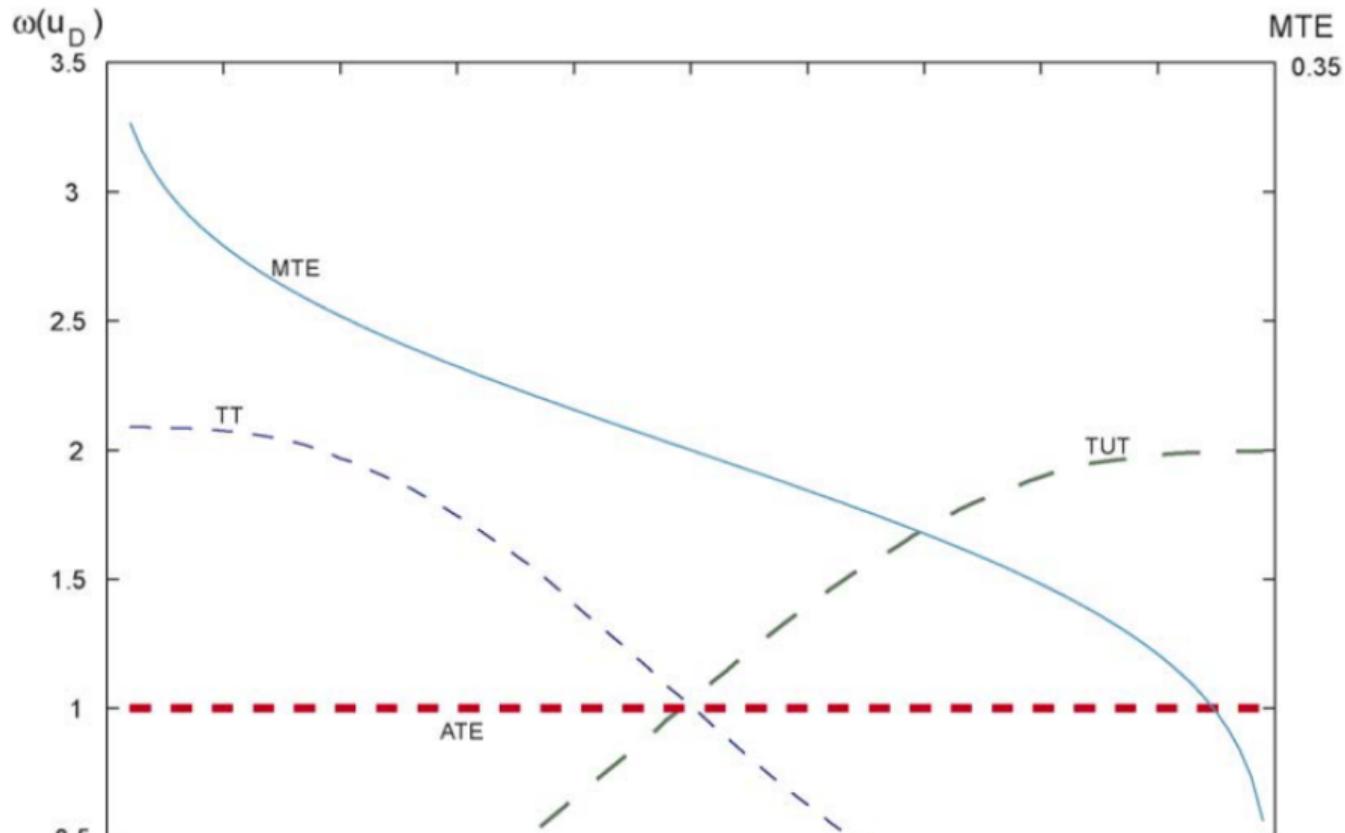

Let D^* be the treatment choice that would be made after the policy change. Let P^* be the corresponding probability that $D^* = 1$ after the policy change. D^* is defined by $D^* = \mathbf{1}[P^* \geq U]$. Let $Y^* = D^* Y_1 + (1 - D^*) Y_0$ be the outcome under the alternative policy. Following Heckman and Vytlacil (2005), the mean effect of going from a baseline policy to an alternative policy per net person shifted is the PRTE, defined when $E(D) \neq E(D^*)$ as

$$(3.1) \quad \frac{E(Y|\text{alternative policy}) - E(Y|\text{baseline policy})}{E(D|\text{alternative policy}) - E(D|\text{baseline policy})} \\ = \frac{E(Y^*) - E(Y)}{E(D^*) - E(D)} = \int_0^1 \text{MTE}(u) \omega_{\text{PRTE}}(u) du,$$

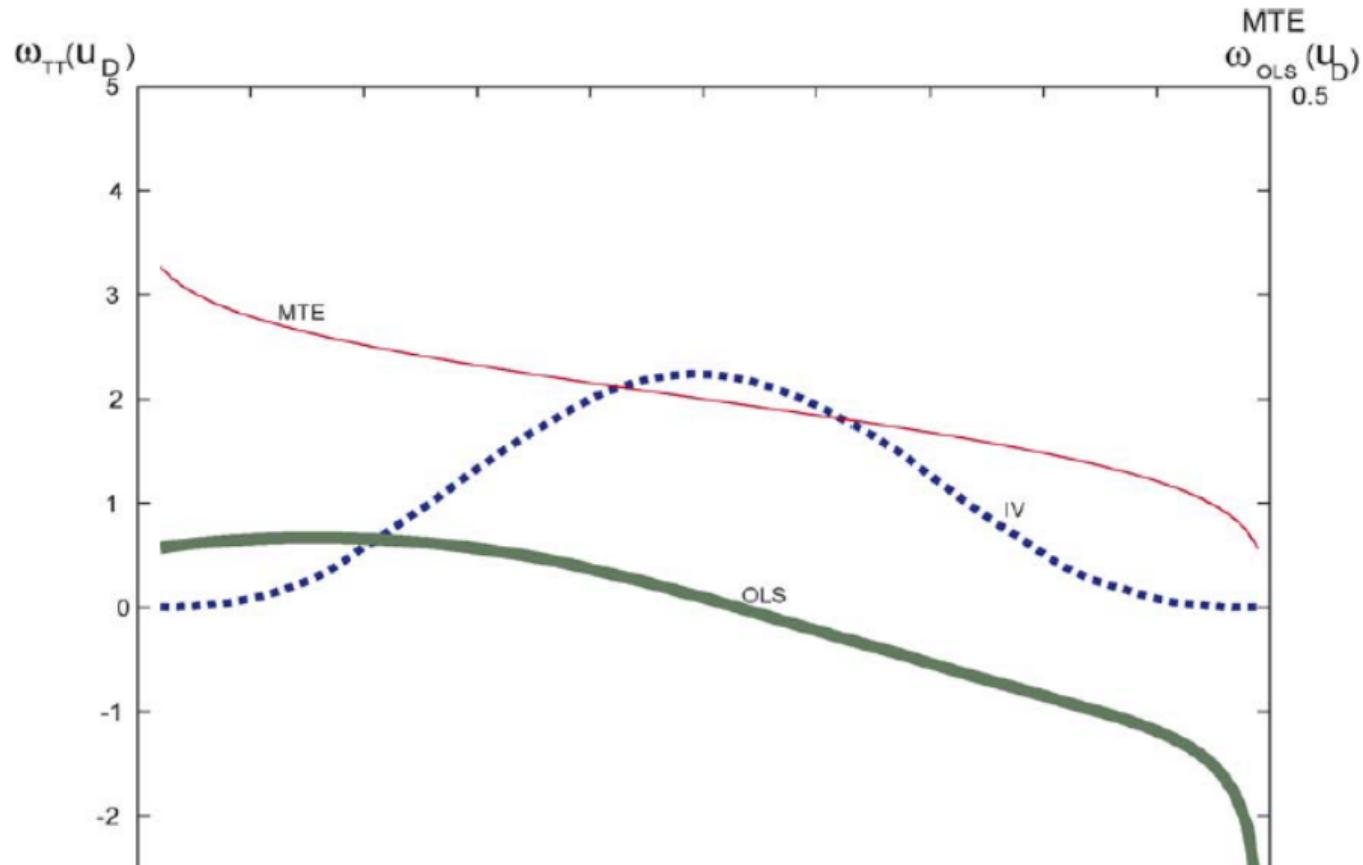

where

$$(3.2) \quad \omega_{\text{PRTE}}(u) = \frac{F_P(u) - F_{P^*}(u)}{E_{F_{P^*}}(P) - E_{F_P}(P)}.$$

CHV Normal Selection Model

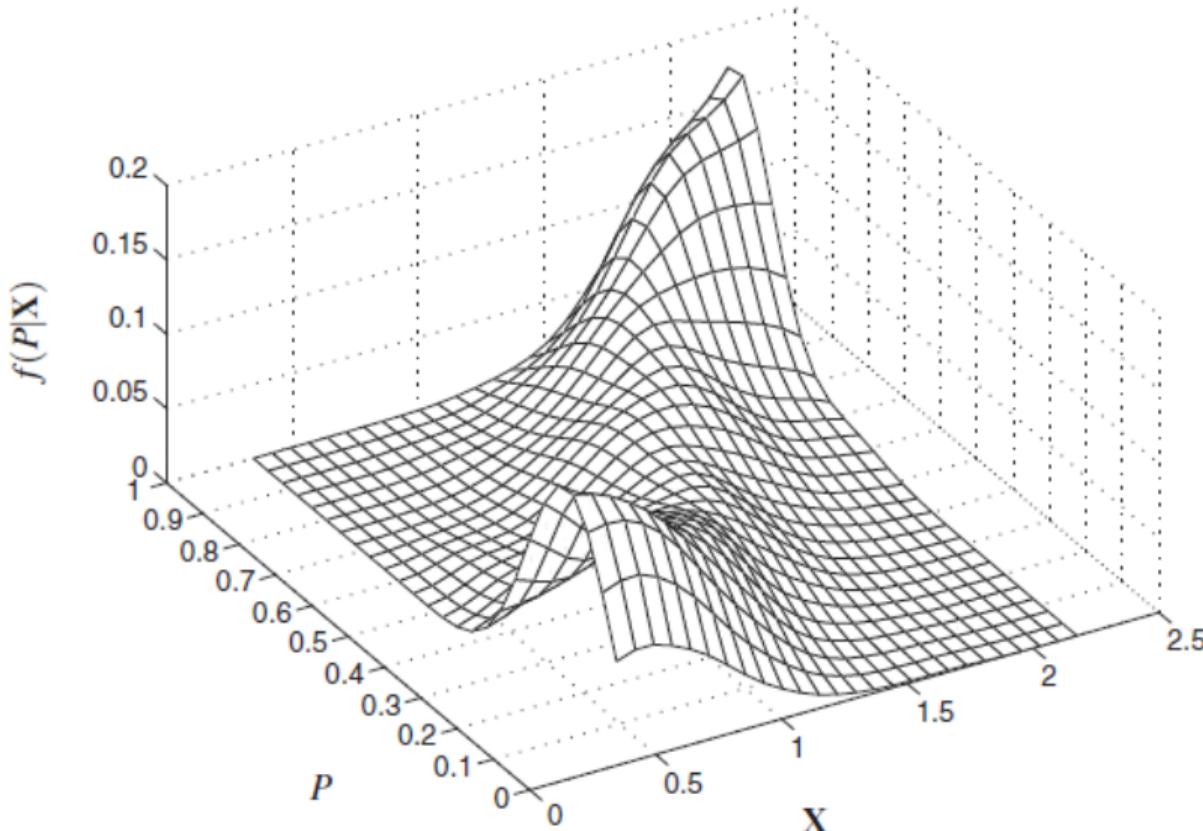

Carneiro, Heckman and Vytlacil

TABLE 5—RETURNS TO A YEAR OF COLLEGE

Model	Normal	Semiparametric
$ATE = E(\beta)$	0.0670 (0.0378)	Not identified
$TT = E(\beta S = 1)$	0.1433 (0.0346)	Not identified
$TUT = E(\beta S = 0)$	-0.0066 (0.0707)	Not identified
MPRTE		
Policy perturbation $Z_\alpha^k = Z^k + \alpha$	Metric $ \mathbf{Z}\gamma - V < e$	0.0662 (0.0373) 0.0802 (0.0424)
$P_\alpha = P + \alpha$	Metric $ P - U < e$	0.0637 (0.0379) 0.0865 (0.0455)
$P_\alpha = (1 + \alpha)P$	Metric $ \frac{P}{U} - 1 < e$	0.0363 (0.0569) 0.0148 (0.0589)
Linear IV (Using $P(\mathbf{Z})$ as the instrument)		0.0951 (0.0386)
OLS		0.0836 (0.0068)

Notes: This table presents estimates of various returns to college, for the semiparametric and the normal selection models: average treatment effect (ATE), treatment on the treated (TT).

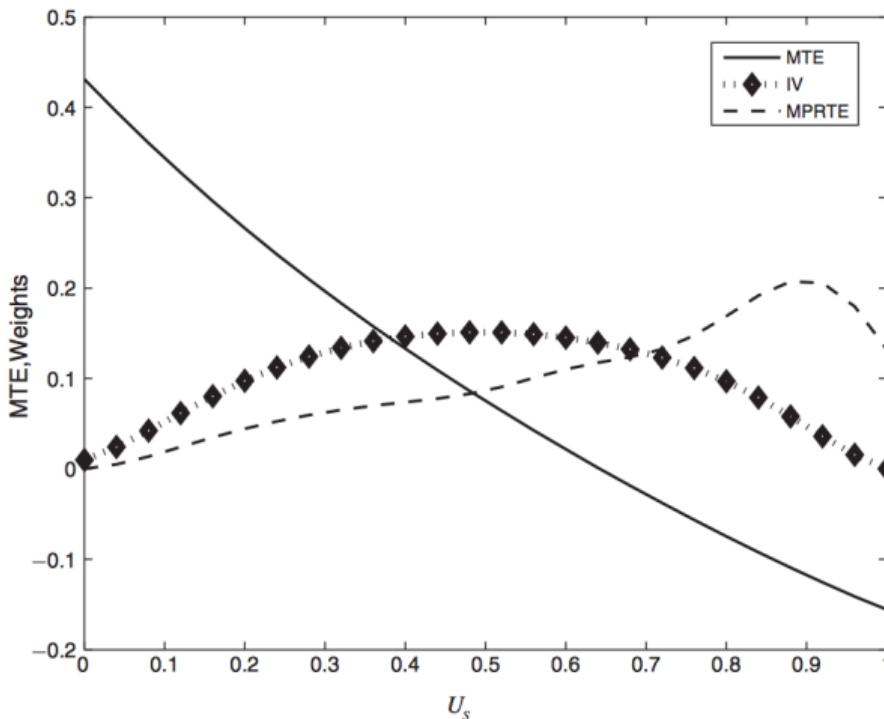

FIGURE 6. WEIGHTS FOR IV AND MPRTE

Note: The scale of the y-axis is the scale of the MTE, not the scale of the weights, which are scaled to fit the picture.

What does this tell us?

- Huge difference in returns
- Negative selection: people with lowest resistance have returns of 40 percent. For those with highest resistance its a 20 percent loss.
- Suggests people know something we don't when they opt out of college.
- Obviously ATE would be very misleading here.

Selection doesn't have to be positive

Cornellissen 2016: universal pre-K program in Germany.

B) MTE curve for returns to early child care attendance

Summary: Margins Matter

Table 1
Treatment effects parameters

	(1)	(2)
	Returns to college	Returns to early child care attendance
ATE	0.067 * (0.038)	0.059 (0.072)
TT	0.143 *** (0.035)	-0.051 (0.080)
TUT	-0.007 (0.071)	0.173 ** (0.085)
IV	0.095 ** (0.039)	0.065 (0.133)

Notes: The table reports the average treatment effect (ATE), the treatment effect on the treated (TT), treatment effect on the untreated (TUT), and the IV estimate from a linear IV specification for the papers presented in Sections 5.1 and 5.2. Column (1) refers to the results reported in Table 5 in Carneiro et al. (2011). Column (2) refers to the results shown in Table 5, column (1) in Cornelissen et al. (2016). Bootstrapped standard errors are reported in parentheses.

Diversion Example

I have done some work trying to bring these methods into merger analysis.

- Key quantity: **Diversion Ratio** as I raise my price, how much do people switch to a particular competitor's product

$$D_{jk}(p_j, p_{-j}) = \left| \frac{\partial q_k}{\partial p_j}(p_j, p_{-j}) / \frac{\partial q_j}{\partial p_j}(p_j, p_{-j}) \right|$$

- We hold p_{-j} fixed and trace out $D_{jk}(p_j)$.
- The **treatment** is leaving good j .
- The Y_i is increased sales of good k .
- The Z_i is the price of good j .
- The key is that all changes in sales of k come through people leaving good j (no direct effects).

Diversion for Prius (FAKE!)

Diversion Example

$$\widehat{D}_{jk}^{LATE} = \frac{1}{\Delta q_j} \int_{p_j^0}^{p_j^0 + \Delta p_j} \underbrace{\frac{\partial q_k(p_j, p_{-j}^0)}{\partial q_j}}_{\equiv D_{jk}(p_j, p_{-j}^0)} \left| \frac{\partial q_j(p_j, p_{-j}^0)}{\partial p_j} \right| dp_j$$

- $D_{jk}(p_j, p_{-j}^0)$ is the MTE.
- Weights $w(p_j) = \frac{1}{\Delta q_j} \frac{\partial q_j(p_j, p_{-j}^0)}{\partial p_j}$ correspond to the lost sales of j at a particular p_j as a fraction of all lost sales.
- When is $LATE \approx ATE$?
 - Demand for Prius is steep: everyone leaves right away
 - $D_{j,k}(p_j)$ is relatively flat.
 - We might want to think about raising the price to choke price (or eliminating the product from the consumers choice set) same as treating everyone!
